G proteins are also involved. TRCs express many second-messenger components common to GPCR-coupled cascades such as cyclic nucleotide and phosphoinositide signaling systems. The effector enzyme phospholipase C $\beta 2$, the second messenger inositol 1,4,5-trisphosphate (IP_3), the IP_3 receptor type 3, and the Ca^{2+} -sensitive transient receptor potential channel TRPM5 all play important roles in the transduction of sweet-, umami-, and bitter-taste stimuli. The role of cyclic nucleotide signaling is less clear, but may contribute to adaptation. The influx of sodium ions via TRPM5 may contribute to the receptor potential and/or mediate neurotransmitter secretion onto afferent nerve fibers, which communicate taste information to the central nervous system.

Glossary

CD3 Complex of polypeptides containing three dimers: $\epsilon\gamma$ heterodimers, $\epsilon\delta$ heterodimers, and, most frequently, $\zeta\zeta$ homodimer (CD247). It is associated with the T-cell antigen receptor (TCR) through charged transmembrane residues and is involved in transducing signals into the T cell upon TCR:peptide–MHC interaction.

Complementarity-determining region (CDR) Areas in the variable regions of antibody and TCR genes. In the TCR, the CDR regions contact the peptide and major histocompatibility complex (MHC) molecule on antigen presenting cells.

Immunoglobulin superfamily Group of proteins that contain immunoglobulin-fold domains of ~100 amino

acids folded into two β -pleated sheets and stabilized by a central disulfide bond. Included in the family are MHC molecules, TCRs, and a number of CD antigens.

Major histocompatibility complex (MHC) A complex of polymorphic genes that encode histocompatibility antigens termed 'H2' in the mouse and 'HLA' in humans. Two main classes of MHC antigens are found as surface glycoproteins on antigen-presenting cells that bind and present peptides to T cells.

T-cell antigen receptor (TCR) Heterodimer of $\text{TCR}\alpha\beta$ or $\text{TCR}\gamma\delta$ expressed on the surface of T cells that is associated with the CD3 complex. The TCR binds to peptide–MHC molecules.

The T-cell antigen receptor (TCR) is a highly organized, multi-molecular complex found exclusively on T and NK T cells. The majority of TCRs are composed of $\text{TCR}\alpha$ and $\text{TCR}\beta$ chains, while a small percentage contain $\text{TCR}\gamma$ and $\text{TCR}\delta$ chains. The TCR chains heterodimerize and are associated with the invariant chains of the CD3 complex, $\text{CD3}\epsilon\gamma\delta$ and CD247 (often referred to as the 'zeta chain', $\text{TCR}\zeta$ or $\text{CD3}\zeta$). Each chain is essential for TCR surface expression and consequently T-cell development and function. This complex mediates the development of T cells that are able to mount a specific immune response against a wide variety of foreign antigens and pathogenic organisms. This unique capability is due to the unusual genomic organization and rearrangement of TCR genes, which generates a vast number of TCRs that recognize almost any antigenic peptide in the context of major histocompatibility (MHC) molecules.

TCR:CD3 Complex: Genes, Proteins, and the Receptor Complex

T-Cell Antigen Receptor

T cells can only recognize and bind antigens when they are presented by MHC molecules, a process called 'MHC restriction'. Initially, the TCR was difficult to study because it was membrane bound and could only recognize antigen in the context of MHC. The first TCR complexes isolated were composed of a disulfide-linked heterodimer of $\text{TCR}\alpha$ and $\text{TCR}\beta$. Monoclonal antibodies against this complex were either specific for a particular T-cell clone or nonspecific, indicating that the TCR chains were similar to the immunoglobulin (Ig) molecules, containing both variable (V) and constant (C) regions. While the vast majority (>95%) of T cells had $\text{TCR}\alpha\beta$ heterodimers, another type of TCR containing a $\text{TCR}\gamma$ and $\text{TCR}\delta$ heterodimer was later identified. The TCR chains, in particular,

the variable regions, are responsible for recognizing and binding to peptide–MHC molecules presented on the surface of antigen-presenting cells (APCs).

Genes: organization and rearrangement

As with antibody molecules, T cells must be able to recognize a wide variety of pathogens; therefore, a diverse repertoire of TCR must be generated that recognize such antigens. Many similarities exist between the Igs and the TCR. The four TCR loci (α , β , γ , and δ) have a germ-line organization similar to that of Ig. The α - and γ -chains are produced by rearrangement of V and J segments, while the β - and δ -chains are produced by rearrangement of V, D, and J segments (Figure 1). The segments for $\text{TCR}\delta$ are located between the $V\alpha$ and $J\alpha$ segments. When the $\text{TCR}\alpha$ gene is rearranged, the $\text{TCR}\delta$ segments are deleted, thereby ensuring that the T cell does not express $\text{TCR}\gamma\delta$ and $\text{TCR}\alpha\beta$ at the same time. The basic domain structure is evolutionarily conserved and is believed to have arisen through gene duplication. Organization of the TCR genes in the mouse and human is similar but varies in the numbers of segments (Table 1).

The TCR genes encode areas of hypervariability similar to the complementarity-determining regions (CDRs) of antibody molecules. Embedded within the V regions are CDR1 and CDR2. There is an additional area of hypervariability (HV4) that does not appear to interact with antigen and is therefore not considered a CDR (Figure 1). CDR3 is a result of VJ or VDJ joining. This intentionally imprecise process frequently results in the addition or deletion of nucleotides, adding significantly to the variability in this region (N region diversity). Occasionally, a nonproductive rearrangement of the first gene locus occurs due to an out-of-frame rearrangement or insertion of a stop codon. This induces the rearrangement of the TCR locus on the other chromosome.

Rearrangement occurs through the action of recombination-activating genes (RAGs) 1 and 2 during T-cell development. Flanking each gene segment in the germ-line DNA are

Figure 1 Rearrangement of TCR $\alpha\beta$ genes. Example of TCR α (bottom panel) and TCR β (top panel) rearrangement. TCR α undergoes V to J rearrangement while TCR β undergoes D to J followed by V to DJ rearrangement. Primary transcripts of rearranged DNA are processed to mRNA that encode the mature TCR $\alpha\beta$ chains expressed on the T-cell surface (center panel, middle). Areas encoding the CDR regions are boxed. TCR δ segments in the TCR α locus are shown in stripes. The center left panel shows a view into the peptide-MHC combining site with peptide in yellow and MHC in green superimposed with the CDR regions (CDR1, 2, and 3; HV4) of TCR α (purple) and TCR β (blue). CDR1 of V α and V β and V β CDR3 are clearly positioned along the central axis of the peptide. N, the N-terminal residue of V α . Reprinted from Garcia KC, Degano M, Pease LR, et al. (1998) Structural basis of plasticity in T cell receptor recognition of a self peptide-MHC antigen. *Science* 279: 1166–1172. The center right panel shows the surface of the TCR-binding site. The surface of the loop trace of the V α CDRs 1 and 2 are purple; CDRs 1 and 2 of TCR β are blue; V α and V β CDR3s are green; and the hypervariable region of TCR β (HV4) is orange. conserved recognition signal sequences. The RAG enzymes recognize these heptamer and nonamer sequences and catalyze the VJ and VDJ joining with a mechanism analogous to that used to rearrange the Ig locus. In addition, secondary rearrangements termed 'receptor editing' or 'revision' can occur in both B and T cells. The role of receptor editing and revision in T cells is still unclear, but it has been suggested to contribute to peripheral T-cell tolerance.

Although many similarities exist between Ig and TCR, there is one important distinction: TCR genes do not undergo somatic hypermutation and thus there is no affinity maturation. While the number of TCR V region segments is dramatically reduced compared to the Ig genes, the number of J region gene segments is greater, increasing the potential diversity at the V-J interface (Table 2). This is likely due to differences in the nature of the antigen recognized by TCR and Ig.

TCR structure and recognition of peptide-MHC complexes

The extracellular domain of the TCR is heterodimeric, with each chain consisting of a membrane-proximal constant domain (Cα and Cβ) and a membrane-distal variable domain (Vα and Vβ), formed by the recombination events described above. Structural analyses of TCRs have shown that the variable domains pair via a conserved hydrophobic core, while the constant domains pair via a highly polar interface, with a skewed distribution of acidic residues in Cα and basic residues in Cβ. In addition, there is a conserved disulfide bond between Cα and Cβ near the membrane (Figure 2). Each C region contains a connecting peptide and a transmembrane domain consisting of several conserved positively charged residues that mediate interaction with the CD3 complex. A very short cytoplasmic tail (5–12 amino acids) is also present at the C-terminal end of both constant domains.

TCRs recognize antigenic peptides in the context of the MHC complex. These complexes are bound to the membrane of antigen-presenting cells, and consist of an anti-parallel β-sheet with α-helices lining the sides, forming a peptide-binding groove (Figure 2). The specificity of a TCR for a particular peptide-MHC complex is determined by the CDRs of the Vα and Vβ domains. The germ-line-encoded CDR2 regions interact primarily with the MHC α-helices, while the highly variable CDR3s are nearly always centered over the antigenic peptide. The CDR1 can interact with the peptide, MHC, or both, depending on the specific interaction. These interactions place the TCR at a conserved diagonal orientation, with the Vα domain interacting with the C-terminus of the peptide and the Vβ domain interaction with the N-terminus, although the angle of this interaction is variable. General hydrophobic interactions between CDR2 residues and the MHC helices are often conserved, but there appear to be no absolute requirements for interactions between specific residues that can account for MHC-restricted binding of TCRs. In addition, there are no significant differences in the binding orientation of MHC class I- and class II-restricted TCRs.

Comparison of TCR-pMHC complex structures with those of unligated TCRs have shown that the CDR loops are flexible, suggesting that conformational adjustment is required during pMHC binding. Most CDR loop adjustments occur in the CDR3s and are in the range of 3–6 Å, although 11 Å is the largest shift observed. Smaller adjustments are often observed in the CDR1s, particularly the CDR1α. The effects of CDR flexibility can account for the typically low affinity ($K_D \sim 1\text{--}100 \mu\text{M}$) of TCRs for their pMHC ligands, which is often the result of a slow association rate. In addition, TCR-pMHC binding is often an entropically unfavorable process, suggesting that the CDRs may become more rigid upon pMHC binding.

Figure 2 TCR:CD3 complex and its interaction with peptide-MHC. Schematic of the presumed stoichiometry of the TCR:CD3 complex. Highlighted are charged transmembrane residues, the ITAM sequence, and the dileucine-based motif. In the upper left panel is a backbone structure of TCR: peptide-MHC complex. TCR is at the bottom and the MHC is on top. The peptide (P1–8) is shown as a large tube in yellow. V α CDRs 1 and 2 are in light and dark purple, respectively; α HV4 in white; V β CDRs 1 and 2, in light and dark blue, respectively; β HV4 in orange; and V α and V β CDR3s in light and dark yellow, respectively. Reprinted from Garcia KC, Degano M, Stanfield RL, et al. (1996) An $\alpha\beta$ T cell receptor structure at 2.5 Å and its orientation in the TCR-MHC complex. *Science* 274: 209–219. In the upper right panel is a ribbon diagram of CD3 γ . The beta strands are in yellow and the text is colored red for CD3 ϵ and blue for CD3 γ . Three pairs of atoms involved in the hydrogen bond formation are designated with amide protons in gray and carbonyl oxygen atoms in red. Two disulfide-linked cysteine residues are shown. Reproduced from Sun ZJ, Kim KS, Wagner G, and Reinherz EL (2001) Mechanisms contributing to T cell receptor signaling and assembly revealed by the solution structure of an ectodomain fragment of the CD3 γ heterodimer. *Cell* 105: 913–923. In the lower left and right panels are the ITAM and dileucine-based consensus motifs, respectively.

Invariant Chains: CD3, CD247, and Pre-T α

CD3 and CD247

The TCR is associated with the invariant chains of the CD3 complex: CD3 ϵ , CD3 γ , and CD3 δ are members of the Ig superfamily with one extracellular Ig domain followed by a transmembrane domain and cytoplasmic tail of ~40 amino acids in length. The zeta family of molecules is unique and has a short extracellular sequence and long cytoplasmic tail. This family consists of CD247 (otherwise known as 'CD3 ζ ' or 'TCR ζ '), its splice variant η , and the γ -chain of the Fc receptor (Fc γ). The CD247 ζ - and η -chains are alternatively spliced gene products and are identical except for the carboxyl-terminal region of the cytoplasmic tail (113 and 155 amino acids long for ζ and η , respectively).

Analysis of CD3 and CD247 knockout mice demonstrates their importance in TCR expression and T-cell development and function. Mice lacking CD247 (CD3 ζ) and CD3 γ exhibit a substantial block in early stages of T-cell development, whereas mice lacking CD3 δ develop a block at a later stage. CD3 ϵ knockout mice display a complete arrest in T-cell development, likely due to its requirement to form heterodimers with CD3 γ and CD3 δ .

The CD3 and CD247 chains contain a number of amino acid residues and motifs that are important for assembly, signal

transduction, and regulation of cell surface expression (Figure 2). The transmembrane regions contain negatively charged amino acids that interact with the positively charged residues of TCR $\alpha\beta$ (CD3 δ , CD3 ϵ , and CD3 ζ -Asp; CD3 γ -Glu). The cytoplasmic tails contain immuno-receptor tyrosine-based activation motifs (ITAMs) that when phosphorylated provide docking sites for SH2 domain-containing proteins, which are important for downstream signal transduction. Each CD3 $\epsilon\gamma\delta$ chain contains one ITAM while CD247 (CD3 ζ) contains three. CD3 δ and CD3 γ also contain a dileucine-based motif. Both the YXXL sequence in the ITAM and the dileucine sequence have been shown to play a role in internalization and downmodulation of many types of receptors from the cell surface. It has been suggested that these motifs are also utilized for TCR transport. A number of studies using T-cell lines *in vitro* have shown a role for the CD3 γ dileucine-based motif in TCR downmodulation; however, its role *in vivo* remains to be defined.

Pre-T α

During T-cell development in the thymus, TCR $\alpha\beta$ precursors express a pre-TCR. The pre-TCR is formed by the functionally rearranged TCR β chain, the CD3 complex, and a surrogate TCR α chain, pre-TCR α (pT α). There are two notable differences between pT α and TCR α . First, pT α only has one invariant

extracellular Ig domain. Second, the cytoplasmic tail of pT α is longer and contains two potential serine and threonine phosphorylation sites and a potential SH3 domain-binding motif. The requirements for surface expression of pT α are still unclear. However, it is clear that a number of signaling events are initiated through the pre-TCR. Pre-TCR signaling confirms the successful rearrangement of TCR β and induces the suppression of further TCR β locus rearrangement, a process called 'allelic exclusion'. Rearrangement of the TCR α locus then occurs leading to progression of T-cell development.

TCR:CD3 Complex

Expression of the TCR on the cell surface requires all six chains of the complex. It is generally accepted that the complex consists of four dimers: TCR $\alpha\beta$ or $\gamma\delta$, heterodimers of CD3 $\epsilon\gamma$ and CD3 $\epsilon\delta$, and a zeta family dimer. The majority of TCR:CD3 complexes (80–90%) contain a CD247 ζ homodimer. Heterodimers of ζ - η or ζ -FcR γ or homodimers of FcR γ have been observed in a small percentage of TCR complexes. An organizing principle has been proposed in which a single negatively charged amino acid in the TCR dimer interacts with two positively charged residues in the CD3 $\epsilon\gamma$, CD3 $\epsilon\delta$, and CD247 ζ dimers. In this model, the TCR α lysine interacts with the CD3 $\epsilon\delta$ dimer, the TCR β lysine interacts with the CD3 $\epsilon\gamma$ dimer and the TCR α arginine interacts with the CD247 ζ dimer.

Role of the TCR in T Cell Biology and Signaling

T-Cell Development

T cells that exit the thymus have been through a selection process based largely on TCR affinity. T cells with TCR that recognize self-peptide–MHC too strongly are negatively selected and deleted. T cells that have too low an affinity to productively interact with self-MHC are ignored and ultimately die of neglect. However, T cells that display a moderate affinity for the self-MHC molecules are positively selected and allowed to exit into the periphery.

Cell Biology

It is known that each of the six protein chains is required for correct assembly and surface expression of the TCR:CD3 complex. Once expressed on the cell surface, the TCR:CD3 complex is constitutively internalized and recycled back to the cell surface via the endosomal network. Once ligated by peptide–MHC complexes, the TCR is downmodulated from the cell surface and diverted to lysosomes for degradation.

Assembly and surface expression of the TCR:CD3 complex

Assembly of the complex is a highly ordered process that takes place in the endoplasmic reticulum (ER). Most of the evidence for assembly order supports a model in which CD3 $\epsilon\gamma$ and CD3 $\epsilon\delta$ heterodimerize followed by sequential addition of TCR α and TCR β chains and the ζ_2 homodimer (or heterodimer). Once the correct stoichiometry is achieved, the intact complex is transported from the ER. It has been shown that the ζ -chain can exit the ER independently of the rest of the

receptor complex and remain in the Golgi complex. CD3 γ and CD3 ϵ have been reported to partly exist as heterodimers in association with calnexin while the TCR α and β -chains have been found to associate with calreticulin. It has been suggested that these molecules may serve as chaperones to prevent the transport of partial complexes. A number of residues are present within the chains that serve as ER retention signals or to target partial complexes to lysosomes for degradation, thereby ensuring that only complete TCR:CD3 complexes are expressed on the cell surface. The charged residues in the transmembrane regions increase their susceptibility to ER degradation. A number of additional residues have been described as possible ER retention or degradation signals; however, a detailed mechanism of complex assembly, including specific interactions between individual chains, remains to be defined.

Internalization and downmodulation of the TCR:CD3 complex

The TCR:CD3 complex is constitutively internalized and recycled back to the cell surface. Although the exact mechanism of this process has not yet been defined, it is likely to involve the interaction of the CD3/CD247 molecules with adaptor protein (AP) complexes that are associated with clathrin at the plasma membrane and intracellular recycling vesicles of the endosomal network. The dileucine-based motif in CD3 γ has been shown to be capable of binding to a member of the AP family of complexes, AP-2. In addition to dileucine based motifs, AP-2 can recognize YXXL-based sequences in a number of receptor systems. Indeed, there is evidence that TCR internalization requires both dileucine and tyrosine-based motifs within the CD3 chains.

Upon ligation with peptide–MHC complexes, the TCR:CD3 complex is downmodulated from the cell surface and recycling is prevented. While the exact mechanism of this important process is unknown, it may involve two related E3 ubiquitin ligases, c-Cbl and Cbl-b, as T cells from mice lacking both proteins fail to downmodulate their TCR following ligation. While both internalization and downmodulation are hallmarks of TCR biology, their physiological importance and function remain to be determined.

Signaling through the TCR

Initiation of T-cell activation occurs when the TCR recognizes peptide–MHC complexes. TCR $\alpha\beta$ consists of the ligand-binding unit while the CD3 complex transduces signals into the T cell. Although initiation of TCR triggering remains unclear, comparative structural studies have offered some evidence for a ligand-induced conformational change model. Structural and fluorescence studies have shown that binding of TCR to an agonist pMHC ligand induces a conformational change within the A–B loop of the TCR C α domain that is reversible upon disengagement of the TCR. Movement of this loop could affect the orientation of CD3 subunits relative to the TCR and initiate signaling. NMR and FRET studies have shown that the cytoplasmic domain of CD3 ϵ is inserted into the plasma membrane in live, nonactivated T cells. Thus, TCR triggering must result in dissociation of the ITAM from the membrane to render the tyrosine residues accessible to kinases. Complete structures of the TCR–CD3 complex would be useful to confirm these models.

Clustering of TCR:peptide-MHC complexes brings in the coreceptors CD8 or CD4 which bind to MHC class I and II molecules, respectively. Both coreceptors are associated with Src-related protein tyrosine kinase (PTK) $p56^{lck}$, while another PTK, $p59^{fyn}$, interacts with the CD3 complex. In resting T cells, these kinases are inactive due to the interaction of the C-terminal phosphotyrosine residues binding to the N-terminal SH2 domain. This intramolecular interaction prevents substrate access to the kinase (SH1) domain. T cell:APC interaction induces the removal of these inhibitory phosphates by the transmembrane phosphatase CD45. Cross-phosphorylation of active site tyrosine residues further potentiates $p56^{lck}$ and $p59^{fyn}$ kinase activity and results in the phosphorylation of the ITAM tyrosine residues in the CD3/CD247 cytoplasmic tails. Phosphorylation of both ITAM tyrosine residues is required for docking of a specialized PTK, zeta-associated protein-70 (ZAP-70), which has two tandem SH2 domains. ZAP-70 kinase activity is further potentiated through phosphorylation by $p56^{lck}$ and $p59^{fyn}$.

Activated ZAP-70 initiates a number of signaling pathways. A key target of ZAP-70 is the raft-resident linker for activated T cells (LAT) which is heavily phosphorylated and recruits a wide variety of downstream signaling molecules. Phosphorylation of phospholipase $C\gamma_1$ ($PLC\gamma_1$) leads to the production of potent second messengers, diacylglycerol (DAG) and inositol triphosphate (IP_3), whose actions lead to protein kinase C (PKC) activation and NF- κ B nuclear translocation as well as Ca^{2+} release and nuclear factor of activated T cells (NFAT) translocation. These events lead to the transcription of genes required for T-cell proliferation and interleukin-2 (IL-2) production. Signaling through ZAP-70 also initiates activation of the Ras pathway and the MAPK signaling cascade which also results in upregulation of genes required for proliferation. A wide array of additional signaling molecules and APs have been shown to contribute to the signaling cascade initiated following TCR ligation and have been reviewed extensively elsewhere.

Advanced microscopic analyses confirmed the biochemical data highlighted above, and have demonstrated that the initiation and regulation of TCR-induced signaling is facilitated by the immunological synapse (IS); a macromolecular structure comprised of TCR:pMHC, CD4/CD8 co-receptors, the co-stimulatory molecule CD28 and its ligands, and adhesion molecules, such as ICAM-1. TCR-induced signaling is initiated in TCR:pMHC microclusters, wherein a single TCR:pMHC complex is sufficient to activate a signaling cascade leading to an increase in intracellular Ca^{2+} levels. Microclusters are subsequently transported laterally toward a central supramolecular activation cluster (cSMAC) which is surrounded by a ring of adhesion molecules, the peripheral supramolecular activation cluster (pSMAC), which are necessary for providing the initial stop signal upon antigenic encounter and which contribute to cytoskeletal remodeling necessary for T cell:APC interactions (Figure 3). Early observations of this prototypical IS comprised of cSMAC and pSMAC regions suggested that it provided the macromolecular organization needed to amplify and sustain TCR:pMHC signals, as evidenced by the accumulation of PKC θ within the cSMAC. However, prevention of microcluster signaling following cSMAC formation has suggested that TCR:pMHC microclusters are responsible for TCR-induced

Figure 3 The morphology and molecular composition of the immunological synapse. (a) MHC-specific $CD4^+$ T cells can be stimulated using synthetic lipid bilayers containing MHC molecules, loaded with fluorescently labeled MHC peptide (pMHC; red), and the adhesion molecule ICAM-1 (blue). Schematic representations (b) and (c) of the immunological synapse include its prototypical bullseye comprised of distinct regions including the cSMAC and pSMAC, which are recognized as distinct areas of signal initiation, amplification, and termination. Reproduced from Sun ZJ, Kim KS, Wagner G, and Reinherz EL (2001) Mechanisms contributing to T cell receptor signaling and assembly revealed by the solution structure of an ectodomain fragment of the $CD3\gamma$ heterodimer. *Cell* 105: 913–923, with permission from Elsevier.

signaling, while the role of the cSMAC is to regulate the strength of TCR signal in part by facilitating TCR internalization and degradation. Indeed, in the mature IS tyrosine phosphorylated signaling proteins, such as ZAP70, LAT and SLP76, are restricted to the pSMAC. Thus, activation of the TCR directs a cell signaling paradigm comprised of distinct biophysical and biochemical events which are tightly coordinated for optimal propagation of signal and T-cell activation. However, it is currently unclear whether there are functional redundancies between CD3 subunits of the TCR:CD3 complex, or if particular CD3 chains or ITAMs are required for mediating distinct aspects of TCR-induced signaling.

Glossary

Adaptive immune response Also known as acquired immunity, it refers to antigen-specific defense mechanisms that take several days to become protective and are designed to react with and remove a specific antigen.

Antigen Any substance capable of eliciting an adaptive immune response is referred to as an antigen.

Autoimmunity The failure of an organism to recognize its own constituent parts as self, which allows an immune response against its own cells and tissues.

Costimulatory receptor A secondary receptor on the surface of a lymphocyte that can influence the development of an effective immune response in addition to the antigen-specific signal from antigen receptors.

Immunological synapse The cell–cell interface between an antigen-presenting cell and a T lymphocyte.

Inflammation A type of nonspecific immune response that serves to recruit other immune components to the site of injury or infection, and often involves redness, warmth, swelling, and pain.

Lymphoma A cancer that originates in a lymphocyte and presents as a solid tumor of lymphoid cells.

Transcription factor A protein that binds to specific DNA sequences to control the transcription of genetic information from DNA into mRNA.

Ubiquitin A 76-amino-acid regulatory protein that can be conjugated to other proteins by specific enzymatic machinery and can mark proteins for destruction or serve as an activating signal.

The Antigen Receptor and the Immunological Synapse

The generation of the adaptive immune response begins with the recognition of the antigen by specialized receptors on T and B lymphocytes. The T-cell receptor (TCR) recognizes peptide antigen displayed by specialized surveillance cells of the immune system known as antigen presenting cells (APCs), such as B cells, macrophages, and dendritic cells. APCs process antigens and present them on the major histocompatibility complex (MHC) for recognition by the TCR. A costimulatory receptor on T cells, known as CD28, is also required for nuclear factor kappa B (NF- κ B) activation. CD28 recognizes B7 molecules on APCs in an important step for the activation of naive T cells. If the TCR binds the peptide/MHC complex in the absence of the costimulatory interaction between CD28 and B7, the cells will fail to fully activate and become anergic and can no longer mount an effective immune response (Figure 1).

The association of many proximal signaling molecules with the TCR occurs at the site of contact between the T cell and APC, known as the immunological synapse. Within the synapse, supramolecular activation clusters (SMACs) provide a spatial and temporal framework for the recruitment and activation of pathway components. There are three subregions of the SMAC that form concentric rings, each defined by the localization of specific molecules. The innermost region is called the central SMAC (cSMAC), and is characterized by the presence of the TCR and several kinases. The cSMAC is surrounded by the peripheral SMAC (pSMAC), which is characterized by the presence of the integrin adhesion molecule LFA-1. The outermost region is the distal SMAC (dSMAC), and contains the tyrosine phosphatase CD45, which is thought to be excluded from the inner regions of the SMAC in order to maintain optimal activation of the receptor-proximal components. The formation of the immunological synapse is

important for the sustained activation of T cells, and may also be important for downstream cellular responses, such as the directional secretion of pro-inflammatory cytokines.

Receptor-Proximal Signaling

Upon antigen binding by the receptor, tyrosine residues within the immunoreceptor tyrosine-based activation motif (ITAMs) on the cytoplasmic tails of various receptor components become phosphorylated. CD3 γ , CD3 δ , and CD3 ϵ each has a single ITAM, and CD3 ζ has 3 ITAMs, each of which has two tyrosine residues that become rapidly phosphorylated by several members of the Src family of tyrosine kinases, which include Lck and Fyn. Lck and Fyn associate with CD45, which removes phosphates from inhibitory tyrosine residues to mediate full activation of these kinases. ITAM tyrosine phosphorylation leads to the recruitment and activation of ZAP-70, a member of the Syk family of tyrosine kinases, via its SH2 domain. ZAP-70 can phosphorylate and activate the TEC family of tyrosine kinases, including ITK and RLK, as well as the transmembrane adaptor protein LAT (linker of activated T cells). LAT tyrosine phosphorylation leads to the recruitment of multiple downstream SH2-containing proteins, including Grb2, PI3K, GADS, and PLC γ 1. A key molecule activated by the costimulatory receptor is the guanine nucleotide-exchange factor Vav, which is tyrosine phosphorylated and membrane localized after its interaction with the adapter molecule Grb2 downstream of CD28 engagement. Vav is also activated, albeit weakly, downstream of TCR engagement. It has been proposed that Vav acts to integrate TCR and CD28 signaling, thereby robustly activating multiple downstream pathways. Costimulatory signaling is also required for the activation of PI3K, which is recruited to and activated by CD28.

Figure 1 T-cell receptor signaling to NF- κ B. Please see text for details.

Second Messengers

The active antigen receptor signaling complex next activates two important signaling proteins, PLC γ and PI3K, which generate important second messengers. PLC γ and PI3K both act upon the membrane lipid $PI(4,5)P_2$ in the generation of second messengers. PLC γ hydrolyzes $PI(4,5)P_2$ into IP $_3$ and DAG, and PI3K phosphorylates $PI(4,5)P_2$ into $PI(3,4,5)P_3$. The IP $_3$ produced can then bind receptors on the endoplasmic reticulum, triggering the release of another key second messenger, Ca $^{2+}$. These second messengers, in turn, can activate multiple downstream pathways, including the Ras/ERK pathway, the PI3K/Akt pathway, and pathways leading to the activation of multiple transcription factors, including NFAT, AP-1, and NF- κ B. For the sake of simplicity, this article focuses on just the signaling pathway that leads to the activation of NF- κ B.

Downstream Activators

The generation of the second messenger DAG is a key upstream event in the activation of the NF- κ B pathway. DAG binds to and activates protein kinase C (PKC) family members, including PKC- θ in T cells. PKCs also require a threonine phosphorylation on their activation loops for full activity. The kinase phosphoinositide-dependent kinase 1 (PDK1) phosphorylates all known PKCs, including PKC- θ , and PDK1 itself is activated by PI3K. In the antigen receptor pathway, a critical phosphorylation target of PKC- θ is the scaffold protein CARD11/CARMA1 (caspase-recruitment domain containing protein 11/caspase recruitment domain (CARD) membrane-associated guanylate kinase (MAGUK) protein 1). A small fraction of CARD11 is localized, in an SH3-domain-dependent manner, at the plasma membrane prior to antigen receptor activation.

Upon TCR engagement, a significant fraction of CARD11 is recruited to the plasma membrane and is localized near the site of receptor activation. A CARD11 mutant in which a residue in the SH3 domain, L808, is mutated to proline does not localize to the plasma membrane and is unable to mediate antigen receptor to NF- κ B signaling, indicating that localization to the membrane is a critical step in the pathway. It is not clear how CARD11 is recruited to the plasma membrane, although ADAP1 (adhesion- and degranulation-promoting adapter protein) and PDK1 have been shown to contribute to CARD11's recruitment to lipid rafts, which are semirigid cholesterol- and sphingosine-rich membrane subdomains where many antigen receptor components and proximal effectors have been found to concentrate. The recruitment to the plasma membrane of several pathway cofactors is dependent upon CARD11, including Bcl10 (B-cell CLL lymphoma 10) and the IKK complex, though it is not clear that plasma membrane recruitment of these cofactors is required for their activity. CARD11 is phosphorylated in a signal-dependent manner at multiple serine residues, including S564, S577, and S654 within its inhibitory domain (ID). The ID has been shown to inhibit CARD11 activity by binding to other signaling domains of the protein, likely blocking their ability to bind downstream cofactors by steric occlusion. Phosphorylation of the CARD11 ID by PKC- θ , and likely other protein kinases, leads to a derepression of its inhibitory activity, allowing multiple signaling cofactors to bind. These cofactors include Bcl10, mucosa-associated lymphoid tissue 1 (MALT1), TNF receptor associated-factor 6 (TRAF6), Caspase-8, TGF activated kinase 1 (TAK1), and the I κ B kinase (IKK) complex. It is thought that the formation of this multi-protein complex is a critical step in the activation of the IKK complex.

IKK Complex Activation

The precise mechanism of IKK activation is not yet fully understood, though several studies have contributed key insights into the potential mechanism. The IKK complex is composed of three subunits: the catalytically active IKK α and IKK β subunits, and the regulatory IKK γ /NEMO (NF- κ B essential modulator) subunit. The formation of the CARD11-containing signaling complex leads to the recruitment of TRAF6 or TRAF2, which are E3 ubiquitin ligases that are thought to be activated upon binding to MALT1. It seems likely that K63-linked polyubiquitin chains play an important role in the activation of the IKK complex, but there is disparate evidence for the way in which these chains are responsible for activation. One study suggests that TRAF6 adds K63-linked polyubiquitin chains to MALT1, and ubiquitinated MALT1 then acts as a docking site for NEMO. A second study suggests that TRAF6 binding to MALT1 causes MALT1 to act as an E3 ubiquitin ligase, inducing the K63-linked polyubiquitination of NEMO itself. NEMO binding to K63-ubiquitinated Bcl10 is also a critical step in the activation of the IKK complex. The E3 ubiquitin ligase responsible for K63-linked Bcl10 ubiquitination has not yet been determined, though the ubiquitination seems to be dependent upon MALT1.

In addition to K63-ubiquitin chain activation, phosphorylation is also important for activity of the IKK complex.

The phosphorylation of the IKK β subunit occurs in a TAK1-dependent manner. IKK β is phosphorylated on serines 177 and 181 in a required step for NF- κ B activation downstream of antigen receptor signaling and other canonical NF- κ B activating pathways. TAK1 has been shown to associate with and phosphorylate IKK β *in vitro*, and chemical inhibition or genetic deletion of TAK1 in cell lines blocks IKK β phosphorylation and NF- κ B activation. Cell-type specific knockout of TAK1 in mice has only partially confirmed the role of TAK1 in this pathway. Deletion of TAK1 in T cells impairs development and NF- κ B activation.

In addition to its adapter and ubiquitin-ligase functions, MALT1's proteolytic activity has been shown to be important for optimal NF- κ B activation. Mutations at MALT1's catalytic site greatly reduce its ability to activate NF- κ B when overexpressed, and chemical inhibition of MALT1's proteolytic activity inhibits TCR-induced NF- κ B activation. Its proteolytic targets include Bcl10 and the negative regulator A20. The cleavage of five amino acids from the C-terminus of Bcl10 by MALT1 is not required for NF- κ B activation, but rather for integrin-mediated T-cell adhesion. The second MALT1 proteolytic target identified is A20, a known negative regulator of other NF- κ B-activating pathways. It is possible that the cleavage of A20 downregulates its inhibitory activity, leading to enhanced NF- κ B activation. A20 has been shown to have both ubiquitin-adding and -removing abilities, and can add both K48- and K63-linked polyubiquitin chains to target proteins. A20 has been shown to promote the removal of K63-linked ubiquitin chains from MALT1 in the TCR pathway, which likely attenuates the interaction between MALT1 and the IKK complex, leading to a downregulation of sustained IKK activity. A20 itself is degraded in a proteasome-dependent manner in an early step of pathway activation, likely in order to allow efficient IKK activation by MALT1. A20 may promote the deubiquitination of multiple pathway cofactors, as TRAF6 and RIP1 are targets in other pathways, and A20 has been shown to bind to IKK γ /NEMO.

In addition to the proteolytic activity of MALT1, the proteolytic activity of Caspase-8 is thought to be required for IKK activation. Caspase-8 has been shown to inducibly associate with CARD11 and TRAF6 upon antigen receptor cross-linking, though its proteolytic target has not yet been identified. Using fluorescent inhibitors, it has been shown that the catalytic activity of Caspase-8 in this pathway is largely restricted to the plasma membrane and lipid rafts, where many pathway components concentrate during signaling.

Interestingly, IKK activity is also important for the downregulation of NF- κ B activity. IKK β phosphorylates Bcl10 in response to TCR signaling, and this phosphorylation leads to the ubiquitination and degradation of Bcl10, thereby reducing the cellular concentration of this required pathway component. NEDD4, Itch, and cIAP2 mediate Bcl10's ubiquitination and subsequent degradation. It is not yet clear how ubiquitinated Bcl10 is degraded, as there is conflicting evidence suggesting that it may be degraded by either the lysosome or 26S proteasome. The role of Bcl10's degradation is likely distinct from the MALT1-mediated proteolytic cleavage of Bcl10, which is a proactivation signal, as discussed above. The protein levels of other pathway cofactors are also downregulated as a means to prevent

sustained pathway activation. The ubiquitin-mediated degradation of ZAP70, Lck, PLC γ 1, PKC θ , and CARD11 has been shown to be involved in turning off TCR signaling.

NF- κ B Activation

The role of the activated IKK complex is to phosphorylate I κ Bs (inhibitors of NF- κ B), which retain NF- κ B in the cytosol to prevent gene transcription by masking nuclear localization signals (NLSs) on NF- κ B. There are nine members of the I κ B family, which can be subdivided into three groups: classical, unusual, and NF- κ B precursors. The classical group, which is the best characterized, is responsible for NF- κ B inhibition in the antigen receptor pathway, and consists of I κ B α , I κ B β , I κ B γ , and I κ B ϵ . The unusual I κ Bs are I κ B ζ , I κ BNS, and Bcl-3. The unprocessed p105 and p100 precursors of NF- κ B subunits p50 and p52, respectively, can act as I κ Bs under certain circumstances. I κ Bs contain five to seven ankyrin repeats that bind to NF- κ B. The IKK β -mediated phosphorylation of I κ Bs at two N-terminal serines signals for their K48-linked polyubiquitination by SCF-family ubiquitin ligase members β TrcP1 and β TrcP2. This polyubiquitination leads to the targeting of I κ Bs to the 26S proteasome for proteolytic degradation. The degradation of these inhibitors leads to the unmasking of NLSs on NF- κ B, allowing NF- κ B to translocate to the nucleus, where it can bind to DNA enhancer elements and activate the transcription of many genes, including proinflammatory cytokines, cytotoxic and anti-apoptotic molecules, and proliferative genes. NF- κ B also activates the transcription of the NFKBIA gene, whose product is I κ B α , thereby forming a negative feedback loop that can turn off NF- κ B activity by binding NF- κ B subunits in the nucleus and relocalizing them to the cytosol.

The NF- κ B family of transcription factors consists of five members, each containing a conserved Rel homology domain (RHD) at its N-terminus: RelA/p65, RelB, c-Rel, p105/p50, and p100/p52. The RHD mediates dimerization, interaction with I κ Bs, and sequence-specific binding to DNA. RelA, RelB, and c-Rel contain a transactivation domain at their C-termini that allow them to activate gene transcription, whereas p50 and p52 lack the ability to activate gene transcription on their own. NF- κ Bs form homo- or hetero-dimers that are held in an inactive state in the cytoplasm by I κ Bs, and can only activate gene transcription when I κ Bs have been degraded.

Pathway Dysregulation: Cancer and Autoimmunity/Inflammation

The mutation or misregulation of several antigen receptor signaling pathway components has been implicated in the

development of several types of lymphomas. Chromosomal translocations that lead to the overexpression of MALT1 and Bcl10 have been linked to MALT1 lymphoma. A chromosomal translocation resulting in the fusion of API2 and MALT1, whose product is known as API2-MALT1, has also been found to be a robust activator of NF- κ B and is associated with the development of MALT lymphomas. At least three genes in this pathway have been shown to be required for the survival of the activated B-cell type of diffuse large B-cell lymphomas (ABC DLBCLs), which is dependent upon constitutive NF- κ B activity for their survival. Activating mutations in CARD11 and the CD79a and CD79b subunits of the B-cell receptors have been found in ABC DLBCL, though it remains to be shown how these mutations lead to the development of the transformed phenotype. In addition, loss-of-function mutations in the deubiquitinating enzyme A20 have been found in a significant fraction ABC DLBCL samples in one study.

This pathway is also an important potential therapeutic target for the treatment of autoimmunity and inflammation, as well as transplant anti-rejection drugs. For example, CARD11 has been shown to be critical for the development of allergic airway inflammation in a mouse model of asthma. The mutations of genes involved in the downregulation of NF- κ B signaling, such as the E3 ubiquitin ligase Itch, are also involved in the development of autoimmunity. A mouse in which Itch is mutated develops spontaneous skin inflammation. The processes involving CARD11 are especially interesting targets for the treatment of cancers and immune disorders, because CARD11 expression is cell-type restricted and is pathway specific, whereas most other pathway components are involved in the activation of multiple pathways leading to NF- κ B in many tissue types. Selective targeting of CARD11 may thus lead to fewer side effects than approaches aimed at inhibiting kinases such as PKC family members or IKKs, or other components of the signaling pathway.

Glossary

Telomerase A nuclear-encoded ribonucleoprotein complex homologous to viral reverse transcriptases that adds single-stranded telomeric repeats to the 3' ends of duplex DNA using its own RNA template; it is responsible for telomere maintenance in most eukaryotic organisms.

Telomere The DNA–protein complex at the extreme ends of linear eukaryotic chromosomes that orchestrates telomere replication and capping.

Telomere-associated sequence (TAS) The highly variable, often repeated DNA sequences found

immediately internal to the terminal simple telomere repeat sequences.

Telomere capping The ability of the telomere DNA–protein complex to prevent chromosome end degradation or fusion (DNA joining) reactions.

Telomeric repeats Simple, short (usually 5–8, but as long as 25 nucleotides) DNA repeat sequences (T₂AG₃ in vertebrates and minor variants in many other eukaryotes) that constitute the DNA component of telomeres. Synthesized by the telomerase enzyme, with the TG-rich sequence extending toward the 3' DNA end.

All linear eukaryotic chromosomes terminate in a specialized nucleoprotein structure, the telomere. Telomeres perform at least two essential functions: they provide (1) a protective cap on chromosome ends that prevents their degradation or deleterious fusion and (2) a special mechanism for replicating the DNA at chromosome ends. In most organisms, telomeres are comprised of a tandem array of simple DNA repeats to which a large set of protein factors are bound. The telomeric DNA repeats are generated by a specialized reverse transcriptase, called telomerase, which uses an endogenous RNA template. Defects in the maintenance of telomeric DNA, for example, through inactivation of the telomerase enzyme, lead to the progressive loss of telomeric repeats and their bound factors, which eventually causes a catastrophic uncapping of telomeres that results in the fusion of chromosome ends. The telomere complex is thus essential to ensure genome stability.

The Telomeric Complex: A Specialized Nucleoprotein Structure at Chromosome Ends

Pioneering studies in the fruit fly and in maize, carried out respectively by H Muller and B McClintock in the early twentieth century, first identified the telomere as a special genetic entity that protects chromosome ends from degradation and fusion, a property absent in DNA ends resulting from random chromosomal breakage. A wealth of subsequent genetic and biochemical studies has led to the understanding that telomeres are specialized nucleoprotein complexes composed of a large number of protein factors assembled onto telomeric DNA.

Telomeric DNA

In most eukaryotes, the terminal DNA sequences at each chromosome are composed of variable-length arrays of simple tandem repeats, first recognized by Blackburn and Gall in the ciliate *Tetrahymena thermophila*. These telomeric repeats are

typically 5–8 nucleotides long, but can be up to 25 base pairs (bp; **Figure 1**), and usually have a higher G content in the DNA strand that runs with a 5'-to-3' polarity toward the end of the chromosome. In all species, the majority of telomeric repeats appear to be in double-stranded form and their total length varies from a few tens of nucleotides in some species of ciliates (e.g., 28 bp of duplex telomeric repeats in *Euplotes*) to tens of thousands of bp in some strains of laboratory mice. In both budding and fission yeasts, telomeres are about 300 bp in length, whereas in human cells telomeres are generally 6–12 kbp long. With the exception of several ciliate species in which the length of telomeric DNA is fixed, in most species the length of each telomere is variable both from individual to individual and during the life of the organism. In many species, it has been shown that telomeres terminate in a single-stranded overhang of the G-rich strand. This overhang can range from only a few nucleotides long (in some ciliates) to about 100–200 bp in mammals, and is believed to represent a general feature of telomeres. G-rich telomeric overhangs *in vitro* can adopt a variety of intra- and intermolecular paired structures, involving most commonly four strands interacting through Hoogsteen-type G–G base-pairing (G-quartets). Mounting *in vivo* evidence for telomeric G-quartets points to a still unclear role for these structures in telomere replication. In mammals, some ciliates, and trypanosomes, telomeric DNA appears to fold back in a structure, the t-loop, where the single-stranded overhang is tucked into the duplex portion of the telomeric tract, by base pairing with the C-rich strand and thus displacing a short portion of the G-strand.

In most organisms, the short telomeric repeats described above are preceded by less conserved DNA elements, called subtelomeric repeats or telomere-associated sequences (TASs). These elements are of variable lengths but are generally at least a few hundred bp long. In any given species, several classes of these repeats can be present, and elements of each class are associated with a particular chromosome with great variation in number and organization. The assembly of these subtelomeric repeats is highly dynamic and subject to active

recombination, resulting in a large variation of subtelomeric regions between strains of yeast or between human individuals. TASs do not appear to carry out an essential telomeric function, as both human and yeast chromosomes that are devoid of them are replicated and segregated properly through both mitosis and meiosis.

Telomerase

DNA polymerases replicate DNA uniquely in a 5'-to-3' direction. As a consequence, as the DNA replication bubble moves along the DNA, the two strands are replicated differently: one strand (the 'leading' strand) is replicated in the same direction as the movement of the replication fork, while the other strand ('lagging' strand) is replicated backward in small installments, each one initiating from an RNA primer laid down by the DNA polymerase 1/primase enzyme (Figure 2(a)). Due to the requirement for an initiating RNA primer, which is later removed, replication of linear DNA molecules by the conventional DNA replication machinery would result in a terminal gap in the lagging strand end at the telomere (Figure 2(a)). The presence of overhangs at telomeres could, in principle, mask this problem at the lagging strand, but a terminal gap would

then occur at the strand replicated by leading strand synthesis after processing of the end to generate the single-stranded overhang (Figure 2(b)). Thus, in the absence of a specialized mechanism to replicate the ends, loss of genetic material is expected to occur at each cell division. The most general solution to this problem in eukaryotes is represented by the specialized replication of telomeric repeats by the telomerase enzyme.

Greider and Blackburn first identified telomerase in the ciliate *Tetrahymena thermophila* based on its ability to add telomeric repeats to a telomeric DNA primer in an *in vitro* reaction. This discovery, together with the demonstration by Blackburn and Szostak that telomeric DNA repeats added onto linear DNA fragments contributed to their stability inside cells, resulted in the award of the 2009 Nobel prize in physiology or medicine to Blackburn, Greider, and Szostak. The telomerase enzyme is in fact a ribonucleoprotein, composed of a protein and an RNA moiety, both of which are required for catalytic function (Figure 2(c)). Isolation of the protein component from the ciliate *Euplotes* by Lingner and Cech in 1997 revealed that telomerase shares extensive homology with reverse transcriptases. Thus, telomerase is a specialized reverse transcriptase that utilizes an endogenous RNA template for the synthesis of telomeric repeats. The enzyme appears to be capable

Figure 2 (a) Schematic view of the end replication problem of a linear DNA molecule. The RNA primers laid down by the primase enzyme for the synthesis of the so-called 'lagging' strand are indicated by thicker blue lines. After removal of the primers, replication of a double-stranded DNA molecule would result in a single-stranded terminal gap in the DNA strand replicated by lagging strand synthesis. (b) Schematic view of the end replication problem at a telomere terminating in a single-stranded overhang. Exonucleolytic resection of the ends is hypothesized to generate the overhangs after replication. In this scenario, a terminal gap would be created in the strand replicated by leading strand synthesis. (c) Representation of the structure of the core telomerase enzyme. The protein, based on its homology to known viral reverse transcriptases, is expected to be folded in a structure with a central cleft (palm) bearing the active site and flanked by two domains (thumb and fingers). The template region of the RNA is placed in this cleft, and the secondary structure of the RNA represented here is derived from ciliated protozoa species and appears to be largely conserved in higher eukaryotes. (d) Representation of the processive mechanism of action of telomerase, where a round of synthesis of telomeric repeats is followed by translocation of the enzyme on the DNA and a subsequent new round of synthesis.

of synthesizing several repeats on a particular substrate through repeated steps of elongation and translocation (Figure 2(d)) and, like reverse transcriptases, appears to be a dimer.

Telomere Proteins

Telomeric repeats serve as binding sites for telomeric DNA-binding proteins, which act as a scaffold for the recruitment of additional protein factors to telomeres, including telomerase (Figure 3). The analysis of telomeric proteins in a wide

range of organisms has revealed important similarities, though significant differences have also emerged.

The major double-stranded DNA-binding activity in budding yeast is Rap1, a protein also involved in transcriptional regulation at many other nontelomeric chromosomal sites. *Saccharomyces cerevisiae* Rap1 binds directly to yeast telomeric repeats through two Myb-like DNA-binding domains. Rap1 is instrumental in recruiting to yeast telomeres a set of proteins involved in telomere length regulation and capping (the Rap1 interacting factors 1(Rif1) and Rif2) and in the assembly of a

Figure 3 Representation of some of the characterized components of the budding yeast and human telomeric complexes. All proteins depicted have been shown either to affect telomere behavior and/or to interact with other telomere components. The fold-back t-loop structure at human telomeres is not indicated in this diagram.

complex (Sir2, 3, and 4 proteins) that results in the transcriptional repression of genes near telomeres (telomere position effect, or TPE). In contrast, mammalian and fission yeast Rap1 appears to be recruited to telomeres indirectly, through the binding to a different class of double-stranded DNA-binding factors, TRF1 and TRF2 in vertebrates and Taz1 in fission yeast. These proteins contain a single Myb repeat that is essential for DNA binding, and bind as dimers. They share among themselves a large domain (TRF homology (TRFH)) that is responsible for homodimerization. Rap1 is recruited to mammalian and fission yeast telomeres through binding with TRF2 and Taz1, respectively. TRF1 recruits the bridging factor TIN2, together with TRF2, as well as tankyrase, a telomeric poly (adenosine diphosphate (ADP)-ribose) polymerase. TIN2, in turn, is responsible for recruiting TPP1 and the single-stranded DNA-binding protein POT1, both of which are

telomerase regulators. The six mammalian telomere-binding proteins, TRF1/2, RAP1, TIN2, TPP1, and POT1, constitute a stable subcomplex that together serves to cap telomere ends, and is referred to as 'shelterin' (see below).

In addition to double-stranded DNA-binding activities, single-stranded DNA-binding factors also appear to be an essential and general feature of telomeres. Overhang binding proteins were initially characterized in ciliates, where they form tenacious salt-resistant complexes with the single-stranded DNA termini. In budding yeast the Cdc13 protein is bound to the single-stranded overhangs created in S-phase in this organism and it carries out essential functions in telomere replication, through interaction with the telomerase and DNA replication complex, and in telomere protection, through interactions with the Stn1 and Ten1 proteins (as part of the Cdc13/Stn1/Ten1 or CST complex). In fission yeast and

mammals, POT1, an ortholog of the ciliate end factors, is involved in telomere protection in fission yeast and in telomere length regulation in mammals. Both Cdc13 and Pot1 bind DNA through an oligonucleotide/oligosaccharide binding (OB) domain. Recently, Cdc13 homologs (CTC1) have been identified in plants, fission yeast, and mammals, as have homologs of Stn1 and Ten1, suggesting that many eukaryotes may use multiple strategies to protect telomeric single-stranded DNA ends.

An additional factor, present at telomeres from yeast to humans, is the DNA repair protein Ku, which might bind to telomeres through its non-sequence-specific DNA end-binding activity. However, protein-protein interactions between Ku and Sir4, and between Ku and TRF2, have been described in yeast and humans, respectively.

Telomeric RNA

It has long been known that telomeric regions in a variety of organisms are in a heterochromatic state that is repressive of the transcriptional activity of nearby genes. In recent years, however, the surprising discovery has been made that telomeric repeats are actively transcribed and that RNA corresponding to the G-rich strand (but not the C-rich strand) accumulates in mammalian cells (Telomeric Repeat-containing RNA (TERRA)). This RNA is associated with telomeres and appears to carry out essential functions in regulating telomere protection and replication.

Telomere Replication

Telomeres are normally maintained through the action of the telomerase enzyme. Although telomerase activity in an *in vitro* assay requires only the reverse transcriptase-like protein motif and the RNA component, it is now clear that the action of the enzyme at telomeres is subject to complex regulation *in cis* at each individual telomere.

Positive Regulation of the Telomerase Enzyme

In budding yeast, a set of genes is required for telomerase activity *in vivo* in addition to the catalytic core components Est2 and Tlc1. These include Est1, which appears to bridge an interaction between telomerase and Cdc13 required to recruit and activate the enzyme at the telomere, and telomerase-associated Est3, whose mode of action is unclear. The combined action of the DNA damage checkpoint kinases Tel1 and Mec1 is also necessary for telomerase activity in budding yeast, possibly by promoting a structural transition in the telomere complex from a closed to an open state that is accessible to telomerase. A similar requirement exists in fission yeast for the Tel1 and Mec1 homologs Tel1 and Rad3. In mammalian cells, a POT1-TPP1 complex may play a direct role in telomerase recruitment. Significantly, budding yeast telomerase action is strictly limited to the S-phase of the cell cycle and requires active DNA replication.

A Negative Regulatory Loop Stabilizes Telomere Length

In cells expressing telomerase, telomere length is maintained around a constant average value that is species specific. Evidence in a variety of organisms has led to the proposal that telomere length is controlled by a negative feedback, protein-counting mechanism. In this scenario, the telomere length regulation machinery somehow senses the number of double-stranded DNA-binding factors that are associated with the telomere at any given time. An increase in the number of these negative regulators results in the inhibition of telomerase activity *in cis* at the telomere (Figure 4). The inhibitory function of the DNA-binding factors (Rap1 in budding yeast, Taz1 in fission yeast, and TRF1/2 in mammals) is apparently mediated by a set of interacting factors (Rif1 and Rif2 in budding yeast, TIN2, TPP1, and POT1 in humans). The precise mechanism of this proposed *cis* inhibition of telomerase is unknown, but might, at least in some organisms, involve formation of the t-loop structure described above.

Telomerase-Independent Maintenance of Telomeres

In the absence of telomerase, alternative pathways for the maintenance of telomeric repeats exist that are based on homologous recombination. In budding yeast, telomere-associated sequences can contribute to this recombinational process. In mammals, several tumor cell lines have been shown to maintain their telomeres without detectable telomerase activity through a mechanism named ALT, for alternative lengthening of telomeres. Finally, the fruit fly *Drosophila melanogaster* dispenses altogether with short telomeric repeats and forms telomeres through the repeated insertion of telomere-specific transposable elements (HeT-A and TART) onto the ends of its chromosomes. In the fruit fly, telomere protection requires the action of proteins involved in heterochromatin formation, and similar mechanisms might be activated in other organisms upon loss of telomerase activity.

Telomere Capping

Telomeres have evolved multiple mechanisms to protect chromosome DNA ends from deleterious degradation of fusion events and to prevent chromosome ends from eliciting a DNA-damage (checkpoint) response. In budding yeast, the CST complex plays a critical role in inhibiting 5' end resection and Mec1-dependent checkpoint activation in G2/M phases. Rif2 also acts to block resection and appears to inhibit Tel1 (ATM) association to telomeres together with Rif1. Rap1, acting through Rif1/2 and/or independently, blocks telomere-telomere fusion by nonhomologous end joining (NHEJ). In mammals, telomere protection is carried out by the shelterin complex (TRF1/2, RAP1, TIN2, TPP1, and POT1), with Rap1 being the only component conserved in budding yeast. The POT1 and TRF2 components of shelterin are dedicated to inhibition of ATM-related (ATR) and ATM action *in cis* at telomeres, respectively, thus preventing either G1/S or G2/M cell-cycle arrest, and subsequent senescence or apoptosis. These two shelterin components also help to block NHEJ and homology-dependent recombination at telomeres, the latter of which appears to be a specialized

Figure 4 Depiction of the protein counting mechanism for telomere length regulation. In this model, longer telomeres have higher numbers of inhibitory factors bound, resulting in repression of telomerase activity *in cis*. Diminished action by telomerase results in telomere shortening, loss of the bound inhibitor, and telomerase activation. In this manner, telomeres are maintained in a state of dynamic equilibrium. The organism in which our understanding of the telomeric complex is the most complete, with regard to both the identification of protein components and their function, is the budding yeast *Saccharomyces cerevisiae* (Figure 3).

function of mammalian RAP1. Finally, the fold-back t-loop DNA structure may play a key role in capping.

Telomerase Repression in Somatic Cells

Implications for Replicative Senescence in Human Disease

Mice engineered to lack the gene encoding telomerase RNA (mTRT) exhibit a gradual (approximately sixth generation) loss of fertility, defects in cell proliferation, and an increase in the frequency of end-to-end chromosome fusions. These phenotypes result from telomere repeat erosion and consequent loss of telomere function. Since active telomerase enzyme is primarily detected in mouse germline cells, these data indicate that telomerase-dependent telomere length re-setting in the germline is essential for long-term survival in the mouse, and by inference in all mammals. In humans, the gene encoding the catalytic subunit of telomerase is also repressed in most somatic cells, causing telomeres to undergo progressive shortening with each cell division. This process leads to cellular senescence in culture and can be reversed, at least in some primary cell lines, by the ectopic expression of an active telomerase gene in the senescing cells. These observations in cultured primary cells have led some researchers to propose that telomerase repression in humans, and consequent telomere erosion, acts as a kind of mitotic clock that determines aging of the whole organism.

The results in the telomerase RNA knockout models have been corroborated by the identification of an increased array of

genetic defects in components of telomerase or in shelterin that result in age-related disorders. The most common of these, dyskeratosis congenita (DC), leads to abnormalities in skin pigmentation and in the oral mucosa, and to nail dystrophy. The most severe outcomes of DC are pulmonary fibrosis, bone marrow failure, and cancer. These clinical manifestations suggest a defect in maintaining the proliferative capacity of adult tissues. In agreement with the idea that telomerase is important in guaranteeing the replicative potential of mammalian cells, a large fraction of DC patients has mutations in either telomerase or the telomerase RNA, or in dyskerin, a telomerase-associated protein. A smaller percentage of affected individuals have mutations in additional telomeric genes, such as the shelterin component TIN2, or the TCAB1 protein, which is required for the proper nuclear localization of telomerase. A second familial syndrome, Hoyeraal–Hreidarsson syndrome, has even more severe phenotypes and is also caused by mutations in dyskerin, telomerase, and TIN2, as well as in the gene coding for the protein Apollo, which has an important role in telomere replication and the processing of telomere single-stranded overhangs.

Telomere Maintenance and Genome Integrity: Telomerase Inhibition as a Tumor Suppressor Mechanism

An attractive view is that the telomere mitotic clock in humans might represent a critical barrier against malignant transformation. Several experiments suggest that either normal telomere

erosion or uncapping caused by mutational alteration of key telomere proteins will induce a DNA-damage checkpoint and apoptosis (programmed cell death). This mechanism may place a limit on continued cell proliferation, which is a prerequisite for tumor formation. However, telomere uncapping also leads to telomere–telomere fusions and rampant genomic instability, which is thought to be a driving force in oncogenesis. Telomere dysfunction might therefore represent an important step in the early stages of tumorigenesis, particularly in cells with compromised checkpoint (DNA damage surveillance) function. The proper regulation of telomerase and telomere capping thus appear to be remarkably critical cellular functions.

Telomerase and Stem Cells

Consistent with its proposed essential function in continued cell proliferation, telomerase activity is also a characteristic feature of stem cells. A wealth of genetic evidence, from both knockout mice lacking telomerase activity and humans with reduced telomerase function, indicates that telomerase plays a key role in stem cell maintenance. In addition to its ability to counteract telomere erosion during cell division, telomerase may also play a role in the stimulation of quiescent stem cells through direct transcriptional effects on Wnt/beta-catenin pathway target genes. Finally, a number of (largely correlative) studies are beginning to reveal effects of stress, at the organismal level, on telomerase activity and telomere length that may have direct consequences for tissue regeneration and aging. These and other studies indicate that telomeres and telomerase, in addition to tumor suppressor links, may have

critical functions in regulatory networks controlling stem cell proliferation and organismal aging.

Glossary

Chorionic gonadotropin (CG) A hormone secreted by the placenta that is nearly identical to the pituitary hormone, luteinizing hormone (LH), and is, therefore, recognized by the LH receptor; also, choriogonadotropin.

Follicle-stimulating hormone (FSH) A pituitary hormone recognized by the FSH receptor; also, follitropin.

Glycoprotein hormones The structurally related hormones thyroid-stimulating hormone (TSH), LH, CG, and FSH.

The glycoprotein hormone receptors are the LH, FSH, and TSH receptors.

Gonadotropins LH, CG, and FSH; members of the glycoprotein hormone family that act upon the gonads. The gonadotropin receptors are the LH and FSH receptors.

G-protein-coupled receptors (GPCRs) A class of membrane receptors that contain seven transmembrane regions and mediate their actions through the activation of G proteins.

Luteinizing hormone (LH) A pituitary hormone recognized by the LH receptor; also, lutropin.

Thyroid-stimulating hormone (TSH) A pituitary hormone recognized by the TSH receptor; also, thyrotropin.

Expression and Physiological Roles of the Glycoprotein Hormone Receptors

The Thyroid-Stimulating Hormone Receptor

TSHR is expressed primarily in the follicular cells of the thyroid. In more recent years, it has also been detected in lymphocytes, thymus, pituitary, testis, kidney, brain, adipose tissue and fibroblasts, heart, and bone.

In response to thyroid-stimulating hormone (TSH), the TSH receptor (TSHR) stimulates the synthesis and secretion of thyroid hormone by the follicular cells of the thyroid. Autoantibodies to the TSHR that are stimulatory are present in individuals with Grave's disease and stimulate the TSHR, causing excessive and unregulated secretion of thyroid hormone. Conversely, inhibitory autoantibodies to the TSHR are found in individuals with Hashimoto's thyroiditis. These antibodies bind to the TSHR and inhibit the binding of TSH, thus blocking the synthesis and secretion of thyroid hormones.

The TSHR present in the adipose and connective tissue of the orbit of the eye is thought to play a role in the development of exophthalmos found in individuals with Grave's disease. Recent studies have also suggested that TSHR present in bone plays a role in bone remodeling. The physiological roles of the TSHR in other nonthyroid tissues are not yet known.

The Luteinizing Hormone Receptor

The luteinizing hormone receptor (LHR) is expressed primarily in the ovaries and the testes. Within the ovary, the LHR is present on theca and interstitial cells and on mature granulosa cells. After ovulation, the granulosa and theca cells of the ruptured follicle differentiate into the luteal cells, and express higher levels of LHR. In males, LHR is expressed on the Leydig cells. In both males and females, nongonadal expression of LHR has also been reported in the reproductive tract and many other tissues.

In the nonpregnant postpubertal female, ovarian theca cells respond to luteinizing hormone (LH) with increased synthesis of androgens, which are used as substrates for estrogen production by follicle-stimulating hormone (FSH)-stimulated granulosa cells. Mature granulosa cells respond to LH with increased progesterone production. In response to the ovulatory surge of LH, the ovarian LH receptors mediate ovulation. If pregnancy ensues, then the LHR of the corpus luteum responds to placental chorionic gonadotropin (CG) with increased progesterone synthesis. As such, the LHR is essential for the maintenance of pregnancy, particularly during the first trimester.

In males, the testicular LHR plays an important physiological role during fetal development. Maternal human chorionic gonadotrophin (hCG) stimulates the fetal Leydig cells to synthesize testosterone, which is required for the differentiation of the external male genitalia and for the descent of the testes into the scrotum. Testosterone levels in boys decrease after birth and the LHR remains unstimulated until the time of puberty. After puberty, the testicular LHR responds to pituitary LH with increased testosterone synthesis.

The physiological roles of nongonadal LHR are not known. It should be pointed out, though, that the only functional consequences detected due to loss-of-function or gain-of-function mutations of the LHR described in males or females have been restricted to abnormalities in reproductive physiology.

The Follicle-Stimulating Hormone Receptor

The follicle-stimulating hormone receptor (FSHR) is expressed in ovarian granulosa cells and in Sertoli cells within the seminiferous tubules of the testes. In postpubertal females, the FSHR mediates follicular growth and controls estrogen synthesis. In postpubertal males, pituitary FSH facilitates spermatogenesis by stimulating the Sertoli cells that are adjacent to the developing sperm to synthesize and secrete components

needed for spermatogenesis. Although it is accepted that optimal spermatogenesis requires the actions of FSH, it is controversial as to whether FSH is essential for this process.

Structural Organization of the Glycoprotein Hormone Receptors

Serpentine Regions

The glycoprotein hormone receptors contain the seven membrane-spanning regions prototypical of the superfamily of GPCRs. Residues that are conserved within the transmembrane (TM) domains of the family A GPCRs are also generally conserved in the glycoprotein hormone receptors. High-resolution crystal structures of rhodopin and other family A GPCRs have provided templates for creating models of the TM regions of the glycoprotein hormone receptors, thus permitting investigators to predict the interhelical interactions maintaining the receptors in their inactive states. The crystal structures also revealed the presence of an eighth α -helix that extends from TM7 and lies parallel to the inner face of the plasma membrane. Helix 8 extends until a palmitoylated cysteine residue and serves to anchor the helix to the plasma membrane. This cysteine is conserved as a single residue or as a pair in the glycoprotein hormone receptors. An alignment of the human TSHR, LHR, and FSHR is shown in [Figure 1](#). The amino acid identity is greatest between the glycoprotein hormone receptors in the transmembrane regions and helix VIII.

Extracellular Domains

A unique feature of the glycoprotein hormone receptors is their relatively large (i.e., 300–400 amino acids) extracellular domains. This is the receptor domain that is responsible for the selective recognition and high-affinity binding of each of the glycoprotein hormones. The extracellular domains are N-glycosylated and a fully conserved tyrosine residue has been shown to be sulfated in the TSHR. The TSHR has the largest extracellular domain and is clipped once the receptor is inserted at the plasma membrane. This proteolytic cleavage results in the formation of an α -subunit containing a portion of the N-terminal extracellular domain and a β -subunit containing the remaining of the N-terminal extracellular domain and the transmembrane and C-terminal domains. Although the α - and β -subunits are initially bound to each other by disulfide bonds, these are reduced and the α -subunit is released from the membrane-bound β -subunit.

The extracellular domains of the glycoprotein hormone receptors consist of a series of leucine-rich repeats (LRRs) followed by a cysteine-rich hinge (linker) region that connects the LRR region to the serpentine domain. The N-terminal portion of the extracellular domain, containing the first LRR, also corresponds to a cysteine-rich region (see [Figure 1](#)). The LRR domain comprises the hormone-binding region of the receptor and the hinge region appears to be necessary for signal transduction. High-resolution crystal structures have been obtained for the hormone-binding domain of the FSHR complexed with FSH and for the TSHR complexed to a TSHR antibody. Each LRR is formed by a β -strand and an α -helix joined by short loops and positioned in a nearly antiparallel

orientation. The tandem arrays of the LRRs form a horseshoe-like structure with consecutive β -strands forming a parallel β -sheet at the concave surface of the horseshoe. FSH is bound to the receptor through contact points with the β -sheets present at the concave surface. The juxtaposition of the hormone-bound FSHR_{HB} relative to the serpentine domain is not known with certainty due to the absence of the hinge region in the structural studies. However, in light of mutagenesis studies, the structural data suggest an orientation that positions the hormone α subunit toward the serpentine domain of the receptor.

Homology cloning and data mining have uncovered additional GPCRs with large extracellular domains containing a variable number of LRRs. Four of these (designated LGR4–8) are found in mammals. Interestingly, the ligands for LGR7 and LGR8, relaxin and/or Leydig cell insulin-like peptide, are structurally homologous to insulin rather than to the glycoprotein hormones.

Dimerization/Oligomerization of the Glycoprotein Hormone Receptors

Each of the glycoprotein hormone receptors can be detected as dimeric and oligomeric complexes in living cells under basal conditions. The propensity for self-association does not appear to be correlated with the activation state of the receptor. Furthermore, the LHR and FSHR have been shown to form dimers and oligomers within the endoplasmic reticulum, suggesting that the organization of the receptors into multimeric complexes is a constitutive process that initiates shortly after biosynthesis and that the receptors are transported to the plasma membrane already self-associated. Both the serpentine as well as the extracellular domains contribute to the dimerization/oligomerization.

Genomic Organization of the Glycoprotein Hormone Receptors

The genes for these three receptors have a similar structure. The LHR gene has 11 exons and the TSHR and FSHR genes each have 10 exons. The last exon codes for a small portion of the N-terminal extracellular domain and the entire serpentine region, including the C-terminal cytoplasmic tail. The other exons are small and they are spliced together to form most of the N-terminal extracellular domain.

The TSHR, LHR, and FSHR genes map to human chromosomes 14q31, 2p21, and 2p21–16, respectively.

Activation of the Glycoprotein Hormone Receptors

G Proteins and Cellular Pathways Activated by the Glycoprotein Hormone Receptors

The identity of the G proteins activated by the FSHR has not been directly examined. The TSHR has been shown to activate all four families of G proteins and the LHR activates at least three or perhaps all four families as well. All of these receptors activate the cyclic adenosine monophosphate (cAMP) and inositol phosphate/diacylglycerol signaling cascades. For each of the glycoprotein hormones, the half-maximal effective

functions of their target cells. The functional consequences of the activation of the inositol phosphate/diacylglycerol pathway are not fully understood. In addition to controlling the differentiated functions of target cells, the glycoprotein hormones also control their proliferation. The three glycoprotein hormones can each activate the extracellular regulated kinase 1/2 cascade (ERK1/2) in their target cells and, at least in the case of the LHR and the TSHR, this activation seems to be

mediated by cAMP. Activation of ERK1/2 also requires the epidermal growth factor (EGF) receptor, but how this is integrated with the cAMP pathway is not well understood and may be target-cell-specific.

Mechanism of Activation

Although it is clear that binding specificity is provided by the large extracellular domains of the receptors and the β -subunits of the hormones, it is not yet clear how the binding of hormone to the extracellular domain leads to receptor activation. Three general models have been proposed. In one model, hormone binding is thought to induce a conformational change in the extracellular domain of the receptor, thus allowing it to interact with and activate the serpentine region. In another model, the common α -subunit of the glycoprotein hormones is thought to directly interact with and activate the serpentine region of the receptor. This model is consistent with that inferred from structural studies of FSH-FSHR_{HB}. The last model proposes that the extracellular domain constrains a constitutive activity intrinsic to the serpentine region and that hormone binding to the extracellular domain relieves this inhibition. This latter model has received experimental support when tested with the TSHR.

Ultimately, agonist binding or constitutively activating mutations are predicted to lead to conformational changes within the serpentine domain that stabilize it in an active conformation. Molecular dynamics simulations based on homology models of the serpentine domains have compared the structures predicted in wild-type receptors and those containing activating mutations. These studies suggest that activating mutations cause an increase in the solvent accessible surface area of the cytoplasmic ends of helices 3 and 6, concomitant with the predicted loss of a salt bridge that links these regions in the resting state.

Human Diseases Associated with the Glycoprotein Hormone Receptors

Autoantibodies to the TSHR

In contrast to the LHR and FSHR, the TSHR can serve as an antigen, eliciting, in some individuals, autoantibodies to the TSHR. Stimulatory autoantibodies to the TSHR cause Grave's disease, a form of hyperthyroidism, whereas blocking autoantibodies (antibodies that bind to the TSHR and prevent the binding of TSH, but do not activate the receptor) cause hypothyroidism.

Naturally Occurring Mutations of the Human Glycoprotein Hormone Receptor Genes

Both activating (gain-of-function) and inactivating (loss-of-function) mutations of the glycoprotein hormone receptor genes have been identified in patients with particular endocrine disorders. Activating mutations of these receptors result in the constitutive activation and unregulated elevation of intracellular cAMP in the absence of bound agonist. Most activating mutations have been found in the serpentine regions of the receptors; however, activating mutations of the TSHR have also been found in the extracellular domain. Germline

mutations resulting in constitutive activation of the glycoprotein hormone receptors are inherited in an autosomal dominant manner.

Loss-of-function mutations refer to a number of different types of mutations that ultimately cause decreased target-cell responsiveness to hormone. These include mutations that impair coupling to G protein, hormone binding, and/or cell surface expression. The majority of loss-of-function mutations of the glycoprotein hormone receptors result in decreased cell-surface expression of the mutant receptor due to the retention of the misfolded mutant in the endoplasmic reticulum. Therefore, loss-of-function mutations have been identified in all regions of the glycoprotein hormone receptors. Mutations of the glycoprotein hormone receptors resulting in a loss of function are inherited in an autosomal recessive manner.

TSHR naturally occurring mutations

A large number of activating mutations of the TSHR have been identified in individuals with autonomously functioning thyroid adenomas (somatic mutations) or autosomal-dominant nonautoimmune hyperthyroidism (germline mutations).

Many loss-of-function TSHR mutations have been identified in individuals with nonautoimmune congenital hypothyroidism, where the degree of hypothyroidism correlates with the extent of target-cell unresponsiveness to TSH.

LHR naturally occurring mutations

Numerous activating mutations of the LHR have been identified in boys with gonadotropin-independent precocious puberty (testotoxicosis). In these cases, the constitutively active human luteinizing hormone receptors (hLHRs) inappropriately stimulate testosterone production in Leydig cells under conditions of prepubertal levels of LH. Only one LHR mutation, D578H, has been found to also cause Leydig cell adenomas. Unlike the other LHR-activating mutations, D578H mutations have been somatic rather than germline in origin. Although it was initially postulated that D578H may activate a pathway(s) different from those activated by the other constitutively active LHRs, such differences have not been observed. Therefore, as with the TSHR, tumor formation by D578H is most likely due to its somatic origin.

Many different loss-of-function LHR mutations have been identified in genetic males with disorders of sexual differentiation, ranging from micropenis (partial loss of function) or pseudohermaphroditism (severe loss of function). In the latter case, the individual presents with female external genitalia but fails to undergo breast development or menstruation at the time of puberty. Female siblings with homozygous or compound heterozygous loss-of-function LHR mutations are infertile.

FSHR naturally occurring mutations

Only one naturally occurring activating mutation of the FSHR in males has been reported. This mutation was found in a hypophysectomized male receiving testosterone supplementation, who exhibited normal spermatogenesis. Studies of this mutant in cell culture, however, have led to disparate results on whether or not it is truly activating. A few activating mutations of the FSHR have been reported in females with spontaneous ovarian hyperstimulation syndrome (OHSS) associated with pregnancy. The OHSS is not due to the constitutive activity of the FSHR, but rather to the fact that constitutively activating

mutations of the FSHR are more readily activated by supramaximal concentrations of hCG than the wild-type FSHR. The increased promiscuous activation by other glycoprotein hormones associated with constitutive activation is unique to the FSHR, as it is not observed with activating mutations of the TSHR or LHR. Activating FSHR mutations have not been found in granulosa cell tumors examined thus far. Nor have they been found associated with nonzygotic twinning. This may be because, in humans, the FSHR exhibits much lower degrees of mutation-induced constitutive activity than the LHR and TSHR.

The first loss-of-function FSHR mutation was identified in a population of Finnish women with primary amenorrhea due to ovarian failure. Cells expressing the recombinant form of this FSHR mutant display no responsiveness to FSH. Surprisingly, men homozygous for this mutation were not infertile, although their fertility may have been impaired somewhat. Therefore, although the FSHR plays an important role in spermatogenesis, these observations raised ongoing debates regarding its absolute requirement. Since then, other loss-of-function mutations of the FSHR have been identified in women with varying degrees of FSH resistance.

Glossary

Apical surface The free surface of epithelial cells facing the luminal space or external environment.

Endothelial cells Thin, flattened cells of mesoblastic origin that are arranged in a single layer that lines the blood vessels and certain body cavities (e.g., those of the heart).

Epithelial cells Closely packed cells arranged in one or more layers that cover the outer surfaces of the body or line internal cavities or tubes except the blood vessels, heart, and serous cavities.

Freeze-fracture replica electron microscopy An electron microscopic method that uses metal replicas to visualize the interior of the cell membranes. This technique provides a convenient way for visualizing the distribution of large integral membrane proteins as intramembranous particles on the plane of a membrane.

PDZ domain Protein–protein interaction domain first described in proteins PSD-95, DLG, and ZO-1.

The Src homology region 3 (SH3) domain A domain commonly found in various signaling proteins.

The tight junction (TJ) (zonula occludens: belt-like TJ) is one mode of cell-to-cell adhesion in vertebrate epithelial and endothelial cellular sheets, where it is located at the most apical part of their lateral membranes. It has a major role in preserving the separation of fluid compartments that have different molecular compositions, which is of great importance for the development and maintenance of multicellular organisms. These compartments are delineated by various cellular sheets, which primarily function as barriers for maintaining their distinct internal environment. Within these sheets, individual cells are mechanically linked to form adherens junctions (AJs), which give the sheet its structural integrity, while the intercellular space between adjacent cells is sealed by TJs to prevent the free diffusion of solutes.

Structure

Electron Microscopic Image

In ultrathin section electron microscopy, TJs appear as a zone where plasma membranes of neighboring cells focally make tenacious contact (Figure 1). In freeze-fracture electron microscopy, they are seen as a continuous, anastomosing network of intramembranous particle strands (TJ strands or fibrils) and complementary grooves.

Three-Dimensional Image

Detailed electron microscopy has provided insight into the three-dimensional structure of TJs (Figure 2). Each TJ strand is associated laterally with another TJ strand in apposing membranes of adjacent cells to form paired TJ strands (kissing points), eliminating any intercellular space. Sometimes ion leaky permeability is formed in TJ strands paracellularly.

Integral Membrane Proteins

Several types of integral membrane proteins are localized at TJs including claudins, TJ-associated marvel domain-containing proteins (TAMPs), and immunoglobulin superfamily proteins

such as junctional adhesion molecules (JAMs), coxsackie and adenovirus receptor (CAR), and endothelial cell-selective adhesion molecules (ESAMs) (Figures 1(c) and 3). Claudins, which have a molecular mass of ~23 kDa, are the major constituents of TJ strands and bear four transmembrane domains. In mice and humans, claudins comprise a multigene family consisting of at least 27 members. When each claudin species is overexpressed in mutant mouse fibroblasts lacking endogenous claudin, several species of claudin molecules polymerize within the plasma membranes to reconstitute paired TJ strands. Since many distinct species of claudins are co-expressed in individual cells, similar copolymerization is thought to naturally occur by heterogeneous combinations of claudins. Claudin molecules may adhere to each other in a homotypic and/or heterotypic manner between adjacent TJ strands.

TAMPs are from a recently defined protein family consisting of occludin, tricellulin, and MarvelD3, which contain marvel-domain (MAL and related proteins for vesicle trafficking and membrane link). Occludin, the first discovered TAMP, has a molecular mass of ~65 kDa and bears four transmembrane domains, although none has any sequence similarity with claudin. Occludin is incorporated into TJ strands *in situ*, but unlike claudin is not necessary for TJ formation. Tricellulin consists of four transmembrane domain-containing integral membrane proteins and is especially concentrated in tricellular TJs. MarvelD3 is the most recently discovered TAMP. Its role is still unclear, but it also appears to regulate TJ barrier function.

Several immunoglobulin superfamily proteins such as JAMs, CAR, and ESAM are also found in TJs. The four JAMs, JAM-A, -B, -C, and -D, associate laterally with TJ strands, but do not constitute the strands. These proteins contain an extracellular region with two immunoglobulin (Ig)-like domains, single transmembrane domains, and short intracellular tails that have a PDZ binding motif.

Peripheral Membrane Proteins

Claudins are packed densely within TJ strands with other membrane proteins, especially at the carboxyl-terminal end.

Figure 1 Structure of tight junctions. (a) Electron micrograph of the junctional complex in mouse intestinal epithelial cells. (b) Schematic drawing of simple epithelial cells. The junctional complex is located at the most apical part of the lateral membranes (encircled). (c) Schematic drawing of the molecular architecture of the tight junction. Claudins are tight junctional membrane proteins that form tight junction strands and ultimately the paracellular barrier. TAMPs are tight junctional membrane proteins that help regulate the tight junctional paracellular barrier function. Immunoglobulin superfamily membrane proteins of tight junctions. TJ, tight junction (encircled); AJ, adherens junction; Des, desmosome. Scale = 200 nm (b) and 50 nm (d).

Figure 2 Three-dimensional image of tight junction strands.

Interestingly, the carboxyl terminal mostly consists of valine, which suggests this is where the TJ binds to PDZ proteins. Therefore, the cytoplasmic surface of a TJ strand can be regarded as a magnetic bar that strongly attracts and recruits several PDZ-containing proteins such as ZO-1/-2/-3, Pals-1, and MUPP-1, all of which are involved in either cell signaling or the cytoskeletal structure. Beginning from the NH_2 -terminus, ZO-1/-2/-3 have three PDZ domains (PDZ1–3), one SH3 domain, and one guanylate kinase-like domain, indicating they are membrane-associated guanylate kinase-like homologs. It is the PDZ1 domain that binds directly to the COOH termini of claudins. Recent studies on ZO-1/-2/-3 have revealed that ZO-1/-2, but not ZO-3, are required for claudins to polymerize and form TJ, and to give the TJ its paracellular barrier function.

In addition, several other PDZ-containing proteins are recruited to the cytoplasmic surface of TJ strands including MAGI proteins and AF-6/Afadin. Moreover, the TJ plaque contains scaffolding proteins that lack PDZ domains and proteins that appear to be primarily involved in regulating signaling at

the TJ, rather than proteins that provide basic structural support. These include several adaptor/signaling proteins such as cingulin and JACOP/paracingulin, the angiomin family proteins angiomin, JEAP and MASCOT, signaling proteins and regulators of small guanosine triphosphatases (GTPases; WNK4), phosphatase (PTEN), Rho GEFs (GEF-H1 and p114RhoGEF), and others (sympleskin). Polarity complex proteins including aPKC, PAR-3, PAR-6, PATJ, and PALS-1 are also integrated into TJs. In addition to these resident proteins, proteins including ZONAB, cdk-4, ZO-2, PAR-6, and huASH1 reportedly localize to both the nucleus and the TJ, and tend to regulate cell proliferation, gene expression, and cell differentiation. Thus, the TJ functions as a supramolecular complex.

Functions

Barrier Function

Claudins are directly involved in the formation and barrier function of TJ strands in epithelia that regulate the movement of not only solutes but also pathogens such as bacteria. Furthermore, TJs are not simple barriers; they show ion and size selectivity, a phenomenon known as 'permeability'. The barrier function varies with the cell type and physiological requirements. Most data suggest the first extracellular loop of the claudin protein creates an electrostatic selectivity filter that controls the overall resistance and charge selectivity of the junction's small pores. Charged amino acid side chains in the claudins minimize the permeability of similarly charged ions in solution without affecting the permeability of oppositely charged ions. Such regulated and diversified permeability is required for dynamically maintaining the environment of each compartment. To explain how materials transport across TJs, aqueous pores (or paracellular channels) have been postulated to exist within paired TJ strands. It is now widely believed that the combination and mixing ratios of claudins

Figure 3 Integral membrane proteins localized at tight junctions. Membrane folding models of mouse claudins, TAMPs, and immunoglobulin superfamily proteins.

within individual paired TJ strands determine the tightness and selectivity of these aqueous pores.

Fence Function

TJ strands are heteropolymers of integral membrane proteins and claudins that continuously encircle the top of individual epithelial/endothelial cells to delineate the border between the apical and basolateral membrane domains. Therefore, it is believed that TJ strands act as a fence, limiting the lateral diffusion of lipids and proteins. Indeed, fluorescently labeled lipids inserted into the outer leaflet of the apical membrane of cultured epithelial cells remain there. In contrast, the importance of TJs in the asymmetric distribution of integral membrane proteins remains controversial. In this respect, ZO-1/-2-deficient cell studies have suggested that even when TJs disappear, the fence function of some proteins is maintained. Thus, the fence function of TJ is under question and it is updated that TJs specifically function as a paracellular barrier.

Claudin Gene Recombinant Mice and Human Diseases

Several claudin genes have been deleted from mice for mutation studies. The resulting changes in permselectivity indicate a permselective barrier role for claudin-1, -2, -5, -11, -14, and -15. On the other hand, deletions of claudin-16 and -19 lead to a phenocopy of their respective human disease mutants and are more easily explained by ion selectivity defects.

Claudin-1 knockout mice show a drastic phenotype of dehydration by destruction of the skin barrier for water. Deletion of claudin-5 resulted in an abnormal blood-brain barrier. Abnormal ion-selective permeability has been seen in the kidneys of claudin-2- or claudin-7-knockout mice. Claudin-11 or -19 induce defects in saltatory conduction due

to mis-sealing nerves. The direct role of claudin in biological homeostasis has been revealed in claudin-2 and -15 knockout mice, which showed a large deviation from ionic biological homeostasis in the intestine and an abnormal transport of nutrients resulting in malabsorption. Furthermore, these abnormal properties resemble those seen in Crohn's disease and ulcerative colitis.

Mice with other knocked-out TJ proteins have also been reported. The knockout of JAMs, for example, showed abnormal immune systems, while knockouts of ZO-1,-2 had lethal embryonic phenotypes. These studies show the importance of tight junctional proteins in disparate biological systems.

Other Possible Functions

Various types of proteins including PDZ-containing proteins are recruited to the cytoplasmic surface of TJ strands to form a huge macromolecular complex. This macromolecular complex is expected to play central roles in the intracellular signaling of epithelial cells by regulating their proliferation and morphogenesis by contact inhibition of cell growth and epithelial cell polarization, respectively.

Glossary

Adaptive immunity Adaptive immunity is also known as specific immunity. It is induced by infectious agents through B and T lymphocytes and characterized by specificity and memory for distinct macromolecules of the pathogen. This immunity has the ability to respond more vigorously to repeated infection of same pathogen.

Chemokines Chemokines are a large family of structurally homologous proteins which stimulate and/or regulate leukocyte movement or trafficking from the blood to tissues.

Cytokines Cytokines are proteins secreted by various cell types (immune and nonimmune cells) that mediate inflammatory and immune reactions. Cytokines are principal mediators of communication between cells of the immune system.

Innate immunity Rapid clearances of the pathogen from the host by the mechanisms that exist before infection are known as innate immunity which essentially is not affected

by the repeated infections. The components of innate immunity primarily consist of two components – the cellular component such as epithelial barriers, phagocytic cells (neutrophils, macrophages), and natural killer cells and the soluble component such as the complement system and cytokines. The regulated and coordinated activities of these components result in eradication of most of microbial pathogen.

Type I interferons Type I interferons (IFNs) are family of antiviral cytokines produced by nucleated immune and nonimmune cells such as macrophages, fibroblast cells, etc., and consist of several structurally related IFN- α and a single IFN- β . Type I IFNs primarily inhibit viral replication. In addition to inhibition of virus replication, type I IFNs also increase the lytic potential of natural killer cells, increase expression of class I MHC molecules on virus-infected cells, and stimulate the development of antigen-specific B and Th1 cells responses.

Introduction

Infection of pathogens rapidly activates various components of host immune system. In metazoan, immune system broadly categorized into two components innate immune system and adaptive immune system. Innate immune system (which is also known as natural or native immune system) is first line of host defense system and consists of innate immune cells such as macrophages, dendritic cells (DCs), neutrophils, etc. These cells express the families of germline-encoded receptors known as pattern recognition receptors (PRRs) which recognize several classes of conserved signature molecules such as proteins, lipid, sugars, nucleic acid, lipo-proteins, glyco-proteins, and glyco-lipids derived from pathogen. These signature molecules are known as pathogen-associated molecular patterns (PAMPs). Recognition of PAMPs by PRRs activate series of biochemical signaling events in innate immune cells to induce inflammatory responses via production of cytokines and chemokines for clearance of the pathogen. The innate immune cells are also critical for the development of pathogen-specific adaptive immunity by instructing lymphocytes.

In last one decade, innate immunobiology was the one of most-studied branch of immunobiology. Till date, several families of PRRs such as Toll-like receptors (TLRs), RIG-I-like receptors (RLRs), NOD-like receptors (NLRs), and C-type

lectin receptors (CLRs) were discovered which play a pivotal role in immune surveillance against bacterial, viral, fungal, and protozoal infection. Among these receptors, TLRs are most extensively studied innate receptor. TLRs in human and mouse were discovered after the discovery of toll protein in *Drosophila* which plays a crucial role in immunity against fungus infection. After discovery of toll in *Drosophila*, homologs of toll protein were identified in several species; in human and mouse 10 and 12 TLR members have been identified, respectively. First nine members of both human and mouse TLR are conserved and recognize same PAMPs except mouse TLR8. The PAMP for mouse TLR8 is unknown and mouse TLR10 has stop codon and nonfunctional. Human TLR10, mouse TLR12, and TLR13 are not well characterized.

TLR PAMPs

TLRs recognize several classes of PAMPs such as protein (flagellin recognized by TLR5; hemagglutinin protein recognized by TLR2), sugar polymer (zymosan recognized by TLR2-TLR6 complex; mannan recognized by TLR4), lipid conjugated with sugar (lipid A, recognized by TLR4-MD2 complex; lipoarabinomannan recognized by TLR2), lipid conjugated with protein or peptide (diacyl lipopeptides recognized by TLR2-TLR6 complex, triacyl lipopeptides recognized by TLR1-TLR2), and

nucleic acid (ssRNA recognized by TLR7 or TLR8; dsRNA recognized by TLR3 and CpG motif of DNA recognized by TLR9) derived from pathogen. Nucleic acid TLR sensors (TLR3, TLR7, TLR8, and TLR9) mainly express and recognize their respective PAMPs in the endosomal or endolysosomal compartment of cells, whereas other PAMPs are recognized on surface of the cells. Several TLRs such as TLR2 recognize the several PAMPs in association with other TLR member such as TLR1 or TLR6. On the other hand, some TLRs such as TLR4 associate with non-TLR member MD2 for the recognition of PAMPs, whereas other TLRs such as TLR3 form homodimers for recognition of their PAMPs. The PAMPs and the pathogen recognized by TLRs are explained in great detail in several reviews and shown in Table 1. In addition to pathogen-derived molecules, TLRs are also reported to recognize endogenous host molecules. TLR2 and/or TLR4 recognize high-mobility group box 1 (HMGB1) proteins, hyaluronic acid, fibronectin, surfactant protein A, and biglycan and induce inflammatory cytokine, and this production was completely abrogated in mice lacking these receptors, although we need to carefully interpret the results considering the possible contamination of bacterial components. In addition to this ligand, endosomal-localized TLRs, TLR7 and TLR9 recognize ribonucleoprotein and chromatin–DNA complexes released from dead cells and have been implicated in the development of systemic autoimmune diseases.

Structure of TLRs

TLRs are type I membrane glycoprotein (the N-terminus of this protein faces extracellular space or endosomal lumen and the C-terminus faces cytoplasm) and consist of ectodomain composed of leucine-rich repeats (LRRs), intermediate domain (spanning cell membrane), and cytoplasmic Toll/interleukin-1 receptor (TIR) domain. Cytoplasmic TIR domain consists of a five-strand β -sheet surrounded by five α -helices. Ectodomain contains several LRRs and each LRR contains 20–30 amino acid. Recently, the crystal structure of ectodomain of TLR1–TLR2, TLR3 and TLR4-MD2 with their PAMP were reported. TLR1 and TLR2 exist as a monomer; however, incorporation of synthetic ligand (Pam3CSK4, containing three lipid chains) induces formation of stable heterodimer of TLR1–TLR2 and activate downstream signaling. The co-crystal of TLR1–TLR2–Pam3CSK4 shows that two out of three lipid chains of Pam3CSK4 were embedded into a hydrophobic pocket in TLR2, whereas remaining one lipid chain was embedded into hydrophobic pocket of TLR1. Both of the pockets are located between the centers of the convex region, suggesting that internal convex surfaces rather than outer concave surface of TLR1–TLR2 heterodimer are important for PAMP recognition.

The crystal structure TLR3 was also reported by two independent research groups; they showed that LRR of TLR3 has horseshoe-shaped solenoid structure. Furthermore, the co-crystal

Table 1 TLR PAMPs and immune responses

TLR	Cellular localization of TLR	TLR PAMPs	Effector immune responses
TLR1/2	Cell surface	Triacyl lipopeptides (Bacteria and Mycobacteria)	Induce inflammatory cytokines
TLR2	Cell surface	Peptidoglycan (Gram-positive bacteria), LAM (Mycobacteria), Hemagglutinin (Measles virus), Phospholipomannan (<i>Candida</i>), Glycosylphosphatidyl inositol mucin (<i>Trypanosoma</i>), Zymosan (<i>Saccharomyces</i>)	Induce inflammatory cytokines, type I IFNs induced inflammatory monocytes after virus infection
TLR3	Endosome	ssRNA virus (WNV), dsRNA virus (Reovirus), RSV, MCMV	Induce inflammatory cytokines and type I IFNs
TLR4	Cell surface	LPS (Gram-negative bacteria), Mannan (<i>Candida</i>), Glycoinositolphospholipids (<i>Trypanosoma</i>), Envelope proteins (RSV and MMTV), Endogenous oxidized phospholipids produced after H5N1 Avian influenza virus infection	Induce inflammatory cytokines and type I IFNs
TLR5	Cell surface	Flagellin (Flagellated bacteria)	Induce inflammatory cytokines, induce differentiation of B cells and naïve T cells to IgA producing plasma cells and Th1 and Th17, respectively
TLR6/2	Cell surface	Diacyl lipopeptides (Mycoplasma), LTA (Streptococcus)	Induce inflammatory cytokines
TLR7	Endolysosome	ssRNA viruses (VSV, Influenza virus), purine analog compounds (imidazoquinolines). RNA from bacteria (<i>Group B Streptococcus</i>)	Induce inflammatory cytokines and type I IFNs
Human TLR8	Endolysosome	ssRNA from RNA virus, purine analog compounds (imidazoquinolines)	Induce inflammatory cytokines and type I IFNs
TLR9	Endolysosome	dsDNA viruses (HSV, MCMV), CpG motifs from bacteria and viruses, Hemozoin (Plasmodium)	Induce inflammatory cytokines and type I IFNs
Mouse TLR11	Cell surface	Uropathogenic bacteria, profilin-like molecule (<i>Toxoplasma gondii</i>)	Induce inflammatory cytokines

LAM, lipoarabinomannan; WNV, West Nile virus; RSV, respiratory syncytial virus; MCMV, murine cytomegalovirus; MMTV, mouse mammary tumor virus; LTA, lipoteichoic acid; VSV, vesicular stomatitis virus; HSV, herpes simplex virus; CpG, cytidine-phosphate-guanosine; IFNs, interferons; ds, double stranded; ss, single stranded; and Ig, immunoglobulin.

structure of TLR3 and its PAMP (46 base pair (BP) double-stranded (ds) RNA) reveal that dsRNA binds with lateral side of the convex surface of TLR3 ectodomain. The first three LRRs at the N-terminus and 19–21 LRRs at C-terminus of LRRs which are rich in positive charge amino acids are essential for the interaction with the sugar-phosphate backbones of dsRNA and it is also required for dimerization and subsequent activation of downstream signaling.

In addition to TLR1–TLR2 heterodimer and TLR3 homodimer with their PAMPs, crystal structure of TLR4 with their agonist (lipid A, an endotoxic component of lipopolysaccharide (LPS), consists of phosphorylated diglucosamine and six acyl chains) or antagonist (Eritoran, consisting of phosphorylated diglucosamine and four acyl chains) has been reported. These studies revealed that MD2 forms an hydrophobic pocket where five acyl chains of lipid A are embedded (in case of Eritoran, all four acyl chains are embedded) and remaining one acyl chain are hanging out side of MD2 and interacts with hydrophobic surface of TLR4 which stabilize the complex for the activation of downstream signaling. Collectively, for effective TLR4-mediated signaling, two copies of TLR4, MD2, and LPS are required. Taken together, all of these studies show the unique horseshoe or 'm'-shape-like architecture and provide the better picture for PAMP-induced TLR dimerization which brings TIR domain to close proximity and induce TIR–TIR domain dimerization for activation of downstream signaling through the recruitment of various signaling adaptors.

TLR Signaling Pathway

TLR signaling mediated by the recruitment of mainly four TIR domain-containing adaptors, namely myeloid differentiation primary response gene 88 (MyD88), TIR-containing adaptor protein (TIRAP)/MyD88-adaptor-like (Mal), TIR-containing adaptor inducing IFN β (TRIF), and TRIF-related adaptor molecule (TRAM). TLR1, TLR2, TLR4, TLR5, TLR6, and TLR11 (mouse) express on cell surface. On the other hand, TLR3, TLR7, TLR8 (human), and TLR9 express in endolysosome. All TLRs except TLR3 recruit MyD88 after PAMP ligation and initiate MyD88-dependent signaling pathway. MyD88-dependent signaling pathway primarily induces inflammatory responses via activation of a transcription factor nuclear factor kappa B (NF κ B) and mitogen-activated protein (MAP) kinases such as extracellular signal-regulated kinase (ERK)1/2, p38, and c-jun N-terminal kinase (JNK). Some TLRs also activate interferon-regulatory factors (IRFs) in DCs and plasmacytoid DCs (pDCs). TLR1, TLR2, TLR4, and TLR6 expressing on cell surface require additional TIR domain-containing adaptor protein, TIRAP, which serves as a bridging protein between TLRs and MyD88. TLR3 recruits TRIF, after ligation with TLR3 PAMP (poly IC), and initiates TRIF-dependent signaling for induction of inflammatory cytokines and type I interferons via NF κ B, MAP kinases, and IRFs activation, respectively. Stimulation of DCs and macrophages with TLR4 PAMP recruits both MyD88 and TRIF via TIRAP and TRAM, respectively, to initiate TRIF-dependent and MyD88-dependent signaling for the induction of inflammatory cytokines and type I interferons. To understand the complexity of TLR signaling, it is categorized into two components, MyD88- and TRIF-dependent signaling (Figures 1 and 2).

MyD88-Dependent Signaling Pathway

Conventional DCs (cDCs) and macrophages stimulated with TLR1/2, TLR2/6, TLR5, TLR11, or TLR4 PAMPs initiate MyD88-dependent signaling through recruitment of MyD88 to the TIR domain of TLR. Upon MyD88 recruitment, interleukin-1 receptor-associated kinase (IRAK) family protein kinases are sequentially activated and recruited (first IRAK4, then IRAK1, and finally IRAK2 is recruited) for the activation of TNF receptor-associated factor (TRAF)6. TRAF6 is an E3 ubiquitin ligase and forms a complex with ubiquitin-conjugating enzymes for polyubiquitination at K (lysine) 63 linkage and unconjugated polyubiquitin chain for the activation of transforming growth factor- β -activated kinase (TAK)1 and TAK1-binding protein (TAB). The activated TAK1 finally activates NF κ B and activator protein (AP)-1 transcription factors through the I κ B kinase (IKK) complex and MAP kinases, respectively, for the transcription of inflammatory cytokines (Figure 1).

Plasmacytoid DCs (pDCs) stimulated with TLR7, TLR8 (human), and TLR9 PAMP induce large amount of type I interferons (an antiviral cytokine). This stimulation leads to the transportation of PAMP to the lumen of endosome; however, in the lumen of endosome PAMP neither binds nor activates the signaling pathway through TLR9 until these TLRs are cleaved or processed. For the processing of TLR9, the endosomes are fused with lysosome to form endolysosome where lysosomal enzymes (cathepsins and endopeptidase) activate TLR9 after proteolysis. The activated TLR9 binds with PAMP and initiates MyD88-dependent signaling pathway for the induction of inflammatory cytokine and type I interferons. Although it is not clear, whether TLR7 also undergoes to the similar processing steps, it has been shown that acidification of endosome is essential for the PAMP recognition by TLR7. UNC93B1 is an endoplasmic reticulum (ER)-localized membrane protein and required for the TLR3-, TLR7-, TLR8-, and TLR9-mediated immune responses because UNC93B1-mutant mice show complete abrogation of cytokines after stimulation with their respective PAMPs. Furthermore; in pDCs, UNC93B1 is required for the transportation of TLR7 and TLR9 from ER to endolysosome after stimulation with TLR7 and TLR9 PAMP. Type I interferons primarily induce through the activation of IRF7 after interaction with MyD88 via IRAKs (IRAK4 and IRAK1), TRAF3, and TRAF6. Moreover, studies reveal that IKK α is also critical for IRF7 activation. In addition of type I interferons, pDCs also induce inflammatory cytokines through MyD88-dependent signaling pathway as explained above. cDCs stimulated with TLR7 and TLR9 ligand induce type I interferons via IRF-1 but require IRF7 (Figure 2).

TRIF-Dependent Signaling Pathway

Conventional DCs and macrophages stimulated with TLR3 and TLR4 PAMPs initiate a TRIF-dependent signaling pathway for the induction of inflammatory cytokines and type I interferons. The TRIF-dependent pathway activates NF κ B and MAP kinases by two different signaling pathways via different domains of TRIF; TRAF6 interacts through N-terminus of TRIF to activate NF κ B and MAP kinases, whereas C-terminus of TRIF harboring receptor-interacting protein (RIP) homotypic interaction motif (RHIM) domain interacts with RIP1 and

Figure 1 TLR signaling in conventional dendritic cells and macrophages. Ligation of PAMP to the TLR initiates TLR signaling pathways in dendritic cells and macrophages. TLR1, TLR2, TLR4 (TLR4 complex with MD2 to form functional receptor), TLR5, TLR6, and TLR11 recognize the PAMP on cell surface and recruit MyD88 to initiate MyD88-dependent signaling pathway, whereas TLR3 recognizes the PAMP in the endosome (TLR3 translocated to the endosome by transporter protein UNC93B1) and recruits TRIF to initiate TRIF-dependent signaling pathway. TLR1, TLR2, TLR4, and TLR6 recruit MyD88 via additional protein known as TIRAP. TLR4 recruits TRIF via additional protein TRAM after translocation into the endosome. Therefore, TLR4 initiates both MyD88- and TRIF-dependent signaling pathway. In the MyD88-dependent signaling pathway, MyD88 interacts sequentially with different IRAK family proteins which activate TRAF6 and this complex activates TAK1. The activated TAK1 activates NF κ B (via the IKK complex) and MAP kinases. In TRIF-dependent pathway, different domains of TRIF interact with TRAF6 and RIP1 to initiate two independent signaling pathways which subsequently culminate to the activation of NF κ B and MAP kinases. TRIF-dependent pathway also induces type I interferons through activation of IKK-related kinases, TBK1/IKKi, which activate IRF3/7, and TRAF3 serves as a linking protein between TRIF and TBK1/IKKi. The activated NF κ B and MAP kinases finally induce transcription of inflammatory cytokines, whereas activated IRF3/7 induces transcription of family of type I interferons.

RIP3. Two additional proteins, TNF receptor-associated death domain (TRADD) and Fas-associated death domain protein (FADD), form a complex with RIP1, and this complex activates NF κ B. The TRIF-dependent pathway also induces type I interferons through activation of IRF3/7. These IRFs are activated by IKK-related kinase, TANK-binding kinase (TBK)1, and IKKi (IKK ϵ) via TRAF3 which serves as a linker between TRIF and TBK1 and/or IKKi. The activated IRFs are translocated to the nucleus and initiate the transcription of type I interferons (Figure 1).

TLRs and Infectious Diseases

TLRs play a pivotal role in innate immune defense; however, contribution of human TLRs in innate host defense in natural infection was not well studied until recently. Patients with MyD88 and IRAK4 mutation were identified and studied; these patients show unresponsiveness to most of TLR PAMPs except TLR3 PAMP. These patients also show increased susceptibility to pyrogenic bacteria, whereas TLR3-deficient patients are prone

to herpes simplex virus (HSV)-1 infection; however, the mechanism for HSV-1 susceptibility is not clear. Furthermore, patients with UNC93B1 deficiency show unresponsive to TLR3, TLR7, TLR8, and TLR9 PAMP. Collectively, these studies suggest that mutations in the genes encoding TLRs and downstream signal transducing molecules influence innate immune responses and increase susceptibility to many infectious diseases.

TLR Agonist/Antagonist Used as Vaccine Adjuvant or Drug

Several TLR PAMPs have been used as a nonspecific stimulator of immune system or vaccine adjuvant. LPS could be used as a vaccine adjuvant; however, due to its high toxicity in human, its use was restricted as an adjuvant. To remove the toxicity of LPS, LPS derivative monophosphoryl lipid A/trehalose dicorynomycolate was developed which has promising vaccine adjuvant properties against infectious disease and hay fever. By contrast, TLR4 antagonists eritoran and resatorvid were introduced for the treatment of sepsis; currently, these

Figure 2 TLR signaling in plasmacytoid dendritic cells. Stimulation of pDCs with TLR7 and TLR9 PAMP causes transportation of PAMP to the endosome (cognate TLR7 and TLR9 were translocated to the endosome by transporter protein UNC93B1). Endosome containing cognate TLR9 undergoes cleavage (activation) after fusion with lysosome to form endolysosome. The cleaved form of TLR9 recognizes PAMP which activates MyD88-dependent signaling pathway for the induction of inflammatory cytokine (same as explained in [Figure 1](#)). For induction of type I interferons, MyD88 associates with IRF7 via the IRAK family of proteins and TRAF3. IKK α also activates IRF7. The activated IRF7 is translocated to the nucleus to induce transcription of type I interferons.

antagonists are in phase I clinical trial. Poly IC (a TLR3 PAMP) and CpG-ODN (a TLR9 PAMP) are also known to be used as a vaccine adjuvant which induces proinflammatory cytokines and type I interferons and also activates strong T-cell responses. Furthermore, these vaccine adjuvants were also proved to be effective in cancer immunotherapy. Imiquimoid and isatoribine, TLR7 agonists are beneficial for the treatment of papilloma-induced genital wart and HCV infection, respectively.

Future Perspective

Incredible progress has been made after the discovery of the TLR in understanding structures of several TLR PAMP–TLR complexes, TLR signaling pathway, as well as regulation of TLR-mediated immune responses. However, it is still unclear that how various innate receptors collaborate with each other and execute complex immune responses via activation of various transcription factors to defend array of infectious diseases. Furthermore, additional studies are required to understand pathogen and TLR interactions in dynamic *in vivo* condition and manipulation of TLR signaling pathways by small molecules to treat various infectious and autoimmune diseases.

Glossary

Cyclobutane pyrimidine dimer The covalent linkage of two adjacent pyrimidines in DNA produced by exposure to ultraviolet light.

Glycosylase An enzyme that cleaves the N-glycosylic bond between a damaged base or inappropriate base and the deoxyribose sugar.

Transcription bubble The unwound DNA structure produced by RNA polymerase in the elongation mode of RNA synthesis.

Nucleotide Excision Repair and Its Subpathways

Several DNA repair pathways have evolved in all organisms to prevent genomic instability generated by persistence of DNA damage. Nucleotide excision DNA repair (NER) is the most versatile excision repair pathway, which recognizes and removes a wide variety of structurally unrelated lesions from DNA, including sunlight-induced cyclobutane pyrimidine dimers (CPDs) and 6–4 photoproducts, cigarette-smoke-induced benzo[a]pyrene DNA adducts, and lesions formed by chemotherapeutic agents such as cisplatin. DNA lesions repaired by NER share the common feature of causing DNA distortions. NER is conserved throughout evolution. In *Escherichia coli*, six proteins are sufficient to carry out NER, while in mammalian cells more than 30 are required. NER involves several steps, including damage recognition, unwinding of the DNA at the site of the lesion, dual incision 5' and 3' to the damage containing strand, removal of a short oligonucleotide containing the lesion, DNA synthesis using, as a template, the complementary undamaged strand, and ligation. Deficiencies in NER result in rare autosomal recessive human disorders such as xeroderma pigmentosum (XP), Cockayne syndrome (CS), UV-sensitive syndrome, and trichothiodystrophy.

NER can be divided into two sub-pathways: global genomic repair (GGR) that recognizes and repairs lesions throughout the genome and transcription-coupled repair (TCR) that specifically operates on lesions located in transcribed regions of the genome (Figure 1).

DNA Damage Recognition in TCR and GGR

GGR and TCR differ in their mode of damage recognition; all subsequent steps are common to both repair pathways. In human cells, the heterodimer XPC/HR23B (XPC, xeroderma pigmentosum group C) appears to be the major damage recognition factor in GGR. The DNA damage-binding protein (DDB) is additionally required for GGR of CPDs, the most common DNA photoproduct generated by exposure to sunlight, so that XPC can be more efficiently recruited to the damaged site. A recently reported crystal structure of a CPD-containing DNA bound to yeast Rad4, a homolog of human XPC, has shed some light on the DNA damage recognition step in GGR. It was shown that both the CPD and the complementary undamaged nucleotides on the opposite DNA strand

are flipped out of the DNA helix. Furthermore, that the CPD lesion is not in contact with the Rad4 protein, which instead recognizes the two flipped-out nucleotides opposite the CPD in the undamaged DNA strand. These findings suggest that both the localized structural change of the double helix at the site of DNA damage and the flipping out of the two base pairs (2 bp) opposite the lesion by the DNA damage recognition protein Rad4 are two key elements in the mechanism of damage recognition in GGR.

In TCR, the initial step of damage recognition is represented by the arrest of RNA polymerase at the site of DNA damage. This is followed by recruitment of TCR-specific factors at the site of arrest and subsequent removal of the lesion by NER enzymes. DNA lesions repaired by TCR include sunlight-induced CPDs and (6–4)PPs, cisplatin DNA cross-links, and DNA adducts formed by benzopyrene-diol-epoxide (Table 1).

Transcription-Coupled DNA Repair

Historically, the initial observation was that UV-induced CPDs in an expressed gene in Chinese hamster ovary (CHO) cells were much more efficiently repaired than those in a silent sequence downstream. Then it was shown that this efficient repair was due to the preferential repair of CPD in the transcribed DNA strand.

For some lesions, like CPDs, TCR results in more rapid repair of the transcribed strands compared to the nontranscribed strands of expressed genes. This strand bias has usually been taken as the operational definition of TCR. However, for other lesions, like the more distorting (6–4) photoproducts, which are very efficiently repaired by GGR, the effect of TCR may not be seen as a differential rate of repair between the two DNA strands.

Several observations indicate that initiation of TCR requires that RNA polymerase is in elongation mode. For example, TCR of the *lac operon* of *E. coli* can only be detected when the operon is induced. In mammalian cells, treatment with α -amanitin, a specific inhibitor of eukaryotic RNA polymerase II (RNAP II), abolishes the preferential repair of CPDs in expressed genes. In yeast, with temperature sensitive mutations in the gene encoding a subunit of RNAP II, TCR is eliminated at the nonpermissive temperature.

Figure 1 Nucleotide excision DNA repair and its subpathways. Nucleotide excision repair is the most versatile DNA repair pathway, dedicated to removal of several different structurally unrelated DNA lesions generated by environmental exposure. Two sub-pathways of nucleotide excision repair have been described: global genome repair (GGR), which removes DNA lesions throughout the genome, and transcription-coupled DNA repair, specific for transcription blocking-DNA lesions located in transcribed strands of expressed genes. GGR and TCR only differ in their mode of damage recognition, all subsequent steps are common to both repair pathways.

TCR does not vary in efficiency, through the normal cell cycle in mammalian cells, for a gene that is expressed continuously throughout the cycle. It is maintained in several differentiated cell types where the GGR pathway is markedly attenuated. TCR does not appear to be inducible by UV. However, in human cells, efficient global genomic repair of CPDs requires activation of the p53 tumor suppressor. Furthermore, growing evidence indicates that arrested transcription (e. g., at CPDs) provides a sensitive signal for the activation and stabilization of p53.

Although TCR was originally documented for DNA damage induced by sunlight, it has also been reported that oxidative damage can be repaired in a transcription-dependent manner, although this conclusion has been the subject of significant debate in the repair field. Recent evidence suggests that it is the presence of RNAP II complexes arrested at abasic sites in transcribed strands that may trigger TCR through recruitment of the NER machinery at the site of transcription arrest.

RNA Polymerase Arrest and Initiation of TCR

The original and still current TCR model proposes that RNA polymerase arrested at a lesion directs repair enzymes to the

transcribed strand of an active gene. This model assumes that the polymerase must be removed from the site of the lesion to provide access of the repair complex to the lesion site and to allow reannealing of the DNA strands to form a proper substrate for repair. In *E. coli*, the *mfd* gene product, encoding a 130-kDa monomeric protein, participates in this process. Using an *in vitro* system with purified proteins, it was shown that the Mfd protein can promote the release of the RNA polymerase and of the incomplete transcript from the DNA template and target components of NER to the site of transcription blockage. Recent evidence has shown that this is accomplished by a forward movement of the polymerase promoted by Mfd in an ATP-dependent fashion until the polymerase dissociates from the DNA. Forward movement is accompanied by a progressive rewinding of the upstream end of the single-stranded-transcription bubble within the transcription complex until the bubble is sufficiently rewound to release the RNAP and the nascent transcript from the DNA, making the lesion accessible for repair.

In mammalian cells, the *ERCC6/CSB* gene product may be such a coupling factor, although the reactions are probably more complex than those in *E. coli*. The cockayne syndrome group B (CSB) gene encodes a 168-kDa protein that is related

Table 1 Correlation between transcription-coupled DNA repair of a lesion *in vivo* and RNA polymerase arrest *in vitro*

DNA lesion	TCR	Transcription arrest	RNA polymerase
Cyclobutane dimer	+	+	T7, <i>E. coli</i> , yeast, rat liver, human

to the SWI/SNF family of ATP-dependent chromatin remodeling factors. SWI/SNF family members such as SWI2/SNF2 are DNA helicases. The CSB protein, like most members of this family, displays DNA-dependent ATPase and DNA-binding activity, but not helicase activity. Similarly, both the bacterial and yeast counterparts of CSB, Mfd and Rad26, are also DNA-dependent ATPases. CSB has also nucleosome remodeling activity and binds to core histone proteins *in vitro*. Furthermore, when added to RNA polymerase arrested at a CPD, CSB can stimulate transcription elongation by addition of one nucleotide (1 nt) to the nascent transcript. It remains unclear whether the polymerase is ubiquitinated and degraded, translocated away from the site of damage without dissociating from the template, or simply stalled at the site of damage while repair of the lesion occurs, as recently suggested. Once the template is repaired, the arrested RNA polymerase might then resume elongation without releasing the incomplete transcript.

Following the initiation of transcription, the template DNA strand is preferentially repaired in the region just upstream of the point at which RNAP II clears the promoter and releases TFIIF in normal cells, in CSA and CSB cells, and in the yeast homolog of CSB. Preferential repair of the transcribed strand beyond the point of TFIIF release requires CSA and CSB or *rad26*, in mammalian cells or yeast, respectively. This suggests that CSB and *rad26* might have a role in re-recruiting TFIIF to the repair complex when the RNAP II is arrested at a lesion while in the elongation mode. In support of this model, it was shown that the RNAP II/CSB complex can interact with subunits of TFIIF *in vitro*. Utilizing another *in vitro* system consisting of an artificial transcription bubble-like structure, it was found that CSB and xeroderma pigmentosum group G (XPG) can bind *in vitro* in a cooperative manner to RNAP II arrested at a cisplatin intrastrand cross-link. Furthermore, the lesion

became accessible to XPG incision only in the presence of wild-type TFIIF and required ATP hydrolysis. It was speculated that ATP hydrolysis by TFIIF would promote a conformational change of the RNA polymerase that would render the damaged DNA accessible for incision by XPG. *In vitro* reconstituted systems were very informative to determine the order of assembly of NER factors at arrested RNAP II complexes. These studies have shown that TFIIF is recruited first and that replication protein A (RPA) binds as soon as single-stranded DNA is formed. Xeroderma pigmentosum group A (XPA) is then recruited to the damage site followed by XPG and xeroderma pigmentosum group F (XPF). In this reconstituted system, CSB appeared to be required for the incision activity. *In vivo* studies revealed that following UV irradiation, RNAP II complexes arrested at UV damage sites are associated with CSB. In agreement with current TCR models, the presence of CSB was also necessary to attract NER factors specific for TCR at sites of RNAP II arrest.

The CSA gene product, which is also required for TCR, is a member of the WD-40 repeat family of proteins that is implicated in protein–protein interactions, but its role in TCR is not known. It was recently shown that CSA is part of an E3-ubiquitin ligase complex consisting of DDB1, Cullin4A, ROC1/Rbx1, and the COP9 signalosome (CSN). The association of the CSA-DDB1/CSN complex with the UV-stalled RNAP complex is dependent on functional CSB protein. Recent evidence indicates that the CSA complex is responsible for CSB ubiquitination and degradation following UV irradiation, establishing a functional link between CSA and CSB proteins.

Two other factors, XAB2 and HMG1, have also been identified and play a role in TCR. XAB2 is a tetratricopeptide repeat (TPR)-containing protein involved in pre-mRNA splicing and transcription and might function as a scaffold for protein complex formation in TCR. HMG1 is a nucleosome-binding protein that was recently shown to interact with UV-stalled RNAP II complexes in a CS-dependent manner and may be required for nucleosome removal behind the arrested polymerase so that the RNAP II can translocate backward from the lesion.

Transcription Arrest at DNA Lesions

To understand the potential roles of the various gene products implicated in the initial steps of TCR, several studies have characterized the properties of the transcription complex when it encounters a lesion in its path. The analysis of different types of arrested complexes has helped to understand how an arrested RNA polymerase may signal the repair proteins to initiate a repair event. In support of the original TCR model proposing that RNAP II arrest at a lesion is a prerequisite for initiation of TCR, a strong correlation between transcription arrest by a lesion *in vitro* and TCR of that lesion *in vivo* has been found in most cases analyzed (Table 1).

Cyclobutane Pyrimidine Dimers

CPDs are the most abundant DNA lesions produced after DNA exposure to ultraviolet light. TCR of CPDs was first

documented in Phil Hanawalt's laboratory in UV-irradiated CHO cells, followed by the finding that the efficient repair of CPDs was due to the preferential repair in the transcribed strand. Using a reconstituted *in vitro* transcription system with RNAP II and initiation factors, it was shown that a single CPD in the transcribed strand is a complete block to mammalian RNAP II progression. In addition, the arrested complex was very stable and could be translocated from the site of damage through the transcript cleavage reaction mediated by elongation factor TFIIS, thus restoring the association of the 3' end of the transcript with the catalytic site of the polymerase after arrest. This result supports a model of TCR in which the backward translocation of the polymerase from the site of arrest may be required for subsequent access to the lesion by repair proteins. In further support of this model, chromatin immunoprecipitation studies have recently shown that, following UV irradiation, TFIIS is associated with the arrested RNAP II.

With the resolution of the crystal structure of *Saccharomyces cerevisiae* RNAP II arrested at a T<>T CPD located in the template strand, new details on the mechanism of transcription arrest at a CPD have been revealed. These studies have shown that RNAP II can correctly incorporate adenosine monophosphate (AMP) opposite the 3' thymine of the CPD, but incorporation of the next nucleotide, opposite the 5' thymine of the CPD is a very slow process, that can only occur if uridine monophosphate (UMP) is misincorporated. This, in turn, causes RNA polymerase to become arrested. Arrest at a CPD is the result of a weak RNA:DNA hybrid formed at the 3' end of the transcript. A stable interaction in the last base pair is necessary to properly orient the transcript 3' end with the incoming nucleotide to form a phosphodiester linkage with the nascent transcript. If the hybrid is weak, bond formation is delayed, allowing the polymerase time to translocate upstream on the template. It is likely that the structural change in the double helix caused by formation of a CPD, consisting of unwinding by $\sim 15^\circ$ and bending of at least 7° relative to the B form may be sufficient to affect formation of the RNA:DNA hybrid, and this in turn may shift the equilibrium from nucleotide addition toward arrest.

Cisplatin-Induced Intrastrand Cross-Links

cis-Diamminedichloroplatinum(II) (cisplatin) is a widely used antitumor drug that preferentially reacts with purine bases to form DNA cross-links. These adducts may impose a more serious problem for an elongating RNA polymerase compared to a CPD, since they cause substantial unwinding and bending of the DNA helix.

It was shown that *cis*-Pt-induced intrastrand cross-links are absolute blocks to RNA polymerase progression. The arrested RNAP II complex is stable, as indicated by the ability of elongation factor TFIIS to induce transcript cleavage. It is likely that the structural changes induced by the *cis*-Pt-induced intrastrand cross-links would affect the formation and/or the stability of the RNA:DNA hybrid, an essential component of the elongation complex.

More insights into the mechanism of RNA polymerase arrest at *cis*-Pt-induced intrastrand cross-link were obtained with the resolution of the crystal structure of a *S. cerevisiae*

RNAP II arrested at this lesion. Different from the mechanism of transcription arrest at a CPD, a *cis*-Pt-induced intrastrand cross-link blocks RNAP transcription because of a translocation barrier that prevents the adduct to enter the catalytic site. This occurs because the two adjacent bases in the *cis*-Pt-induced intrastrand cross-link are covalently linked and, as a result, cannot twist by approximately 90° as required for the incoming base to enter the polymerase active site.

Oxidative DNA Damage

Several *in vitro* studies aimed at characterizing the behavior of 8-oxoG and thymine glycol (Tg) on RNAP transcription have shown various levels of RNAP bypass at these lesions. Elongation factors have been recently shown to have a significant role in modulating readthrough past these lesions, suggesting that the differences in the *in vitro* transcription results that are previously observed may have derived from differences in the cell extract used, and/or on the presence of elongation factors among components of the transcription system. Elongin and CSB, which affect the rate of RNAP II elongation, but not TFIIS, which help arrested complexes to bypass transcriptional blocks, were shown to stimulate bypass of Tg, whereas Elongin, CSB, and TFIIS could all enhance readthrough of an 8-oxoG lesion. Furthermore, transcription past these lesions caused misincorporation opposite the lesion, suggesting that elongation factors, by promoting readthrough past 8-oxoG or Tg, could contribute to the transcriptional mutagenesis induced by these lesions.

If 8-oxoG and Tg do not represent a significant barrier to RNAP transcription *in vitro*, how can they elicit TCR *in vivo*? It was initially proposed that RNAP pausing at 8-oxoG could be sufficient to initiate TCR. Another possibility is that intermediates in the repair of oxidative damage such as natural abasic sites may be sufficient to elicit TCR. *In vitro* studies aimed at addressing this question have shown that abasic sites, 2-deoxyribonolactone, an oxidized form of the apurinic/apyrimidinic (AP) site, and its caged precursor, when located in the transcribed strand of template DNA, were strong blocks to T7 RNAP and mammalian RNAP II. Based on the current TCR model postulating that only lesions that block RNAP will be subject to TCR, these findings suggest that the abasic site and its oxidative derivative may be sufficient to initiate TCR *in vivo*. In agreement with this prediction, recent findings indicate that AP sites in transcribed strands trigger TCR *in vivo*.

Perspective

After more than 20 years since the discovery of transcription-coupled DNA repair, we are starting to have a better understanding of the steps leading from arrest of transcription at the site of damage to repair of the lesion and transcription restart. However, we still do not know how the coupling between transcription arrest and initiation of TCR occurs. In addition, it is unclear what determines whether a lesion will block transcription or which features of an RNAP arrested at a lesion make it a substrate for repair with respect to a polymerase arrested at a natural arrest site or at a noncanonical DNA structure.

The development of novel approaches for studying TCR will help to address some of these challenging questions.

Glossary

Backtracking Reverse translocation of RNAP along the DNA template. The RNA is re-threaded through the enzyme with the 3' end emerging into the secondary channel and an internal phosphodiester linkage in the active site.

Polarity Loss of transcription of a downstream gene in an operon due to transcription termination within an upstream gene in the same operon; transcription termination in the upstream gene is usually a result of failed or stalled translation, allowing access of Rho to the RNA and RNAP.

RNA/DNA hybrid An RNA and a DNA strand paired in an A-form 8 or 9 bp double helix with the main channel of RNA polymerase.

Termination Release of the nascent transcript from RNA polymerase; it is unclear if transcript release and enzyme dissociation are necessarily coupled.

Transcription elongation complex An active complex of RNA polymerase, its nascent transcript, and the associated DNA template.

Introduction and Background

RNA synthesis by DNA-dependent RNA polymerases (RNAPs) is processive, requiring a single enzyme molecule to transcribe the full length of a gene regardless of the length. The requirement for RNAP to remain resolutely associated with the DNA template through multiple kilobases necessitates an extremely stable transcription elongation complex that can transcribe through different sequences and protein-bound DNA templates. Despite this stability, cells must be able to halt RNA synthesis after transcription of a complete gene or operon, and stop any RNAP that has initiated transcription aberrantly. Failure to terminate transcription of an upstream gene could allow regulation-independent expression of downstream genes, and synthesis of untranslated or antisense transcripts with detrimental consequences; aberrant transcription is particularly problematic for the gene-dense chromosomes common to Bacteria and Archaea. Two general mechanisms have evolved to efficiently disrupt transcription elongation complexes that release the RNA transcript and recycle RNAP for further rounds of transcription.

Multi-subunit RNAPs from each domain share a near identical core structure that envelopes an 8- or 9-bp RNA:DNA hybrid within a tight-fitting pocket (Figure 1). High-resolution crystal structures and a wealth of biochemical data from many different RNAPs demonstrate that hydrogen bonding within the hybrid and contacts between the enclosed nucleic acids and RNAP provide stability to transcription elongation complexes. Despite similar transcription elongation complex architecture, RNAPs from different domains, and each of the eukaryotic RNAPs, respond to different termination signals and factors, suggesting that several mechanisms of transcription termination are possible, or that a diverse set of factors and sequences use a common mechanism to disrupt the complex. Conserved elongation factors (i.e., NusG and NusA) modify RNAP activities and add an additional level of regulation to the elongation–termination decision. The mechanistic details of transcript release are best understood in Bacteria, although some features are shared in each domain. This article focuses on transcription termination and its regulation in

Bacteria, with relevant comments to bring attention to similarities and differences in Archaea and Eukarya.

Bacterial Transcription Termination

Two general mechanisms of transcription termination have been characterized in both biochemical reactions with purified components and through genetic experiments. The first, termed 'intrinsic termination', requires only defined template sequences and the resultant RNA transcripts to disrupt the transcription elongation complex. The second, factor-dependent termination, requires the activity of an additional protein that interacts with the transcription elongation complex.

Intrinsic Termination

Intrinsic terminators are composed of two essential elements: (1) a ~10–20 bp region of dyad symmetry in the DNA which is transcribed into an RNA sequence capable of forming an RNA–RNA duplex or RNA hairpin structure and (2) a T-rich sequence that directs the synthesis of a uridine-rich sequence in the RNA immediately following the RNA hairpin (Figure 2). Base pairing within the stem of the hairpin, the presence of the uridine-rich segment, and the spacing of these elements are critical to termination efficiency; flanking sequences can also influence the efficacy of specific terminators. Transcript release occurs 8–10 bp downstream of the 3' base of the hairpin, typically near the end of the uridine-rich sequence.

A combination of factors leads to transcript release, although the mechanics of RNA release may occur via several mechanisms. The transcription elongation complex is weakened by sequence context alone; the hybrid at the normal position of termination is predominantly rU:dA, providing only the weakest hydrogen bonding of all possible combinations of nucleic acids. The uridine-rich sequence serves a second role, to pause RNAP at the position of termination, and any sufficiently uridine-rich sequence has been shown to direct RNAP to pause. The paused, weakened transcription elongation complex is now positioned immediately adjacent and downstream of the region capable of

Figure 1 The bacterial transcription elongation complex. Upper panels (top view), with RNAP movement from left to right. Lower panels (front view), with RNAP movement right to left. RNAP (gray), RNA (yellow), template strand (cyan), nontemplate strand (orange). Panels (a)/(d) – surface representation of the bacterial transcription elongation complex. The encapsulated nucleic acids are fully enclosed within the complex. Panels (b)/(e) – as (a)/(d), respectively, with one RNAP subunit (b) removed to reveal the interior of the elongation complex and the path of the enveloped nucleic acids. Panels (c)/(f) – cartoon depiction of the bacterial transcription elongation complex. Sections of RNAP are shown partially transparent to show the hidden nucleic acids.

Figure 2 An intrinsic terminator. The DNA sequence of the t_{82} intrinsic terminator is shown in black, with regions of dyad symmetry shown in bold and underscored by arrows. Asterisks mark the known positions of RNA release. The resultant RNA is shown in red, with base-pairing indicated, and the known 3' terminal bases shown in bold.

hairpin formation, and RNAP interaction with the RNA hairpin results in transcript release.

The role of hairpin formation and its effects on the elongation complex are debated, although most models predict that hairpin formation disrupts the upstream bases of the hybrid, triggering collapse of the transcription elongation complex and

RNA release. RNAP can be pushed forward by hairpin formation, and in the absence of continued synthesis, such movement unwinds the hybrid and eliminates RNAP-hybrid interactions necessary for complex stability. Hairpin formation has also been shown to direct changes in RNAP structure. Allosteric models of transcription termination predict relatively

large structural changes in RNAP that reduce the stability of the complex, hinder further synthesis, and allow dissociation of the complex.

Intrinsic termination also occurs in the Archaea and Eukarya, although this differs in detail from bacterial intrinsic termination. Archaeal RNAPs and eukaryotic RNA polymerase I or III (Pol I or Pol III) do not require an RNA hairpin for intrinsic termination, although each enzyme does terminate transcription, *in vivo* and *in vitro*, in response to oligoT-rich template sequences. For these RNAPs the exact sequence of the oligo-T-rich region, its flanking sequences, and general sequence context dictate termination position and efficiency. Evidence suggests that oligo-T-rich sequences first evolved as termination sequences, and remain so for many RNAPs, with RNA hairpins adding specificity and precision to bacterial intrinsic termination. Eukaryotic RNAP polymerase II (Pol II) is notably resistant to bacterial intrinsic termination sequences and appears completely dependent on auxiliary proteins for transcription termination.

Factor-Dependent Termination

Many genes and operons lack easily identifiable intrinsic termination sequences. Genetic and biochemical evidence demonstrates that termination of their transcription relies on proteins that disrupt the transcription elongation complex. The activity of these factors is also generally employed for all transcription units, regardless of whether an intrinsic termination signal is also present.

Rho-mediated termination

Rho is an RNA-dependent ATPase encoded in most bacterial genomes, but not in Archaea or Eukarya. Rho is a surveillance factor that monitors the normal coupling of bacterial transcription and translation. Rho accesses transcription elongation complexes by binding to ribosome-free RNA, wrapping ~60 nts of RNA around a ring-shaped hexameric structure. Since RNAP elongates at ~50–100 nucleotides per second, Rho provides a rapid response to the uncoupling of transcription and translation. Its mechanism of action is to translocate along the RNA and physically disrupt the elongation complex. Rho normally targets transcription elongation complexes that have reached the end of genes or operons, and thus are uncoupled from translation via ribosome release at the stop codon, but Rho can disrupt any elongation complex that is not immediately and consistently trailed by a ribosome, and is therefore responsible for polarity.

The major function of Rho may be to suppress futile transcription of host genes and limit expression of any introduced phage or foreign genes. Rho-dependent termination also is the natural mechanism of release at certain sites, likely serving as the sole mechanism to terminate transcription of many operons. Properties that favor Rho action are the absence of translation, a cytidine-rich transcript, and the absence of secondary structure. These characteristics are sufficiently common for Rho to engage any elongation complex that is not closely followed by translating ribosome. Release of a nascent transcript is, in principle, possible at all promoter-distal locations, but release is normally only seen at sites that direct RNAP to pause, likely allowing Rho to catch up to the elongation complex. Strong

secondary structures in the RNA can impede Rho binding and activity. Rho action is stimulated by NusG and limited by NusA (see below).

The accepted mechanism of Rho activity invokes movement along the RNA until RNAP is reached, then pulling the RNA out of the elongation complex; alternatively, RNAP may be pushed forward, or allosterically modified to release the transcript. Recent work suggests that Rho may interact with RNAP throughout the transcription cycle *in vitro*, and thus be poised to halt transcription immediately in the absence of translation; stoichiometric details of this interaction are not known, nor has this proposed mechanism been evaluated *in vivo*.

The absence of Rho in eukaryotes is not surprising given the physical separation of transcription and translation. Archaea are prokaryotes with transcription and translation coupled, and decoupling leads to polarity, but the protein(s) responsible are yet to be biochemically characterized.

Mfd and transcription-coupled DNA repair

Repair of highly transcribed DNA is more rapid than noncoding or poorly transcribed DNA. Furthermore, the template strand is repaired faster than the nontemplate strand of the same gene. DNA damage on the template strand stalls RNAP, and so a single lesion in an essential gene could prove deadly. RNAP stalled at the position of the DNA lesion serves as a marker of that lesion and recruits a factor (Mfd) that initiates RNAP removal and DNA repair. Mfd is a DNA-dependent helicase that binds directly to RNAP and rewinds the DNA duplex at the upstream edge of the transcription elongation complex, injecting torque that collapses the transcription bubble, moves RNAP forward, and ultimately disrupts the elongation complex. If RNAP is only stalled or backtracked, Mfd activity can rescue the elongation complex to an active configuration. When continued elongation is blocked by a DNA lesion, the elongation complex is removed, and Mfd then recruits the UvrABC complex to excise the lesion and initiate DNA repair. Like Rho, Mfd can terminate transcription of almost any elongation complex.

Transcription-coupled DNA repair also occurs in Eukarya and requires the transcription-repair coupling factor. To date, there is no experimental evidence for transcription-coupled DNA repair in the Archaea.

Elongation Factors

NusA and NusG are nearly universally conserved in Bacteria and homologs of both are found in almost all Archaea and Eukaryotes. NusG in particular is well represented in all three domains, consistent with an early evolution and the necessary role of this general elongation factor. Both factors bind directly to RNAP, both influence the elongation rate of RNAP, alone and in combination, and both are normally essential in Bacteria. In *E. coli*, removal of remnant phage sequences from the genome can relieve this essentiality; NusG (Spt5), but not NusA, is essential in Archaea and Eukaryotes.

In a purified system, NusA generally slows elongation, enhances pausing, and increases intrinsic termination efficiency. NusA has RNA-binding domains, and may interact with RNA hairpins and enhance interactions between RNA hairpins and RNAP. In simple terms, NusG has the opposite

functions: it enhances elongation and limits pausing. It should be noted that NusG proteins from different Bacteria have been characterized with different activities in a purified system. NusA and NusG can influence RNAP activity at the same time, and although their effects on RNAP activity balance to some degree, each still exerts discrete effects on RNAP activity during elongation. NusA and NusG also influence Rho activity. Strong Rho-dependent termination sites are pause sites but the effects of NusA and NusG on Rho function are opposite to those predicted based on their effects on pausing. NusA promotes pausing but inhibits Rho function, whereas NusG inhibits pausing but promotes Rho function. RNAP pausing is only one component underlying the efficiency of Rho-dependent termination, and the interplay of NusA and Rho activity is emphasized by the ability of a NusA defective cell to survive if Rho is also defective.

Biochemical and structural information regarding the binding sites of NusG and NusA on RNAP have bolstered the role of these factors in modifying RNAP activity, and demonstrated the universal nature of these interactions in each domain. NusG and NusG-related proteins bind to RNAP across the main channel, interacting with the nontemplate DNA strand of the elongation complex, bridging the clamp and lobe domains of RNAP, and effectively enclosing the DNA within the RNAP-factor complex. This enclosure may provide additional stability to the elongation complex and promote continued elongation. NusA interacts with the C-terminal domain of the alpha subunit of bacterial RNAPs and can directly bind to the core body of RNAP near the exit channel for the nascent RNA. NusA, unlike NusG, does not appear to directly enclose or provide stabilizing interactions between RNAP and the enveloped nucleic acids.

Regulated Termination and Antitermination

Efficient transcription termination is often solely thought of as a necessity for controlled expression in compact genomes, but regulation of upstream transcription termination is often employed to regulate downstream gene expression. As with termination, antitermination can be based primarily on sequence information (intrinsic) or reliant on protein factors.

Site-Specific Antitermination: Attenuators and Riboswitches

Upstream intrinsic termination is used to regulate expression of many operons through mechanisms that alternatively permit or prevent transcription termination in a leader sequence or initially translated region (Figure 3). Alternative RNA structures (e.g., a Riboswitch or Ribosensor) in the nascent transcript dictate whether transcription continues or is terminated based on the formation or lack of formation of a terminator structure in the RNA. The RNA fold that forms is influenced in most examples by small molecules (i.e., metabolites, cations, and tRNAs) that directly bind to the RNA and affect folding. Both positive and negative transcription-based riboswitches have been described. Classical riboswitches rely on interactions with small molecules to dictate RNA structure, although examples of protein-influenced riboswitches are known.

As a term, attenuation is most often reserved for translation-coupled regulation of intrinsic termination, whereby positioning of a trailing ribosome influences formation of a downstream terminator. The classical example of such regulation is found in the *trp* operon, where stalling of the ribosome at tryptophan codons, due to limited availability of charged aminoacyl-tRNA^{Trp}, determines which sequences of the transcript can hybridize, and thus whether a terminator hairpin can be formed. Examples of riboswitches and attenuators have been described for Eukaryotes. However, although the prokaryotic Archaea appear poised to take advantage of these systems, there is no evidence for such regulation.

Termination and Antitermination Factors

Transcript-specific regulatory factors, such as the lambdaoid phage N and Q proteins, the bacterial RfaH protein, and the phage HK022 Nun protein, regulate expression of those genes by altering the termination capacity of RNAP. Specific RNA sequences within the nascent transcript can also form structures that interact with and change the termination potential of RNAP. In general, these factors are recruited to particular transcribing RNAPs via *cis*-acting nucleic acid sequences. Exact

Figure 3 A termination-based Riboswitch. Both panels depict a transcription unit (arrow marks the promoter; DNA in black; RNA in red with sections of sequence highlighted in green, blue, and yellow; RNAP is shown as a gray translucent sphere) with a long leader sequence encoding a Riboswitch upstream of a gene (orange). A fold of the nascent transcript is influenced by binding, or lack thereof, of a small molecule (purple star). Hybridization of the yellow and green RNA sequences results in formation of an intrinsic terminator.

details of the mechanisms and resultant modifications to the elongation complex stability are only just beginning to be described. λ N and HK022 Nun proteins bind to essentially the same RNA structures, but have opposite effects: λ N, in combination with other host factors including NusA and NusG, interacts with RNAP to stimulate elongation through downstream terminators and promotes phage gene expression. By contrast, binding of HK022 Nun protein to this same structure blocks continued elongation, thus preventing superinfection of its host by another lambdoid phage that requires N function for growth. Nun-modified complexes are halted, but not disrupted by Nun action, and thus Nun is not a release factor. Nun-arrested complexes require the activity of the Mfd protein to efficiently release RNAP and the nascent transcript.

RfaH and λ Q proteins require *cis*-acting DNA sequences to pause RNAP at discrete sites and present unique complexes for interaction. Both factors attach to the elongation complex, becoming integral components of a now terminator-resistant complex. λ Q protein interacts with RNAP at a promoter-proximal pause and likely remodels the active site of RNAP and strengthens interactions between RNAP and the hybrid to resist the action of a terminator. RfaH, a homolog of NusG, regulates expression of select operons by interacting with RNAP facilitated by a regulatory pause site (*ops* sequence) that stimulates expression of distal genes. RfaH interactions with RNAP mimic those of NusG, providing stability to the complex by further enveloping the nucleic acids and forming a bridge across the main channel of RNAP.

Published by Elsevier Inc.

Glossary

Calcium channels Protein(s) that mediate passive, electrochemical gradient-driven, flux of calcium.

Ca²⁺ signaling Events that initiate elemental changes in cellular levels of Ca²⁺ which are then decoded into a physiological response.

Channelopathy Disease directly linked to channel structure and function.

Human disease Disease related to disruptions in human systems that translate into dysfunction.

Ligands Small molecule or other reagents that gate ion channels.

Neurotransmitter Chemical messengers secreted by nerve endings.

Introduction to Transient Receptor Potential Channels

The transient receptor potential (TRP) superfamily of cation channels represents a remarkable group of ion channel proteins that display a wide array of ion permeabilities and diverse activation mechanisms. TRP channels have been shown to play critical roles in the physiological function of cells as well as in pathophysiology and disease. This versatile family of ion channels respond to all major classes of external stimuli, including sensory (temperature, mechanical, and osmolarity), chemical ligands (tastants, flavors, noxious chemicals, and natural products) as well as endogenous stimuli (such as neurotransmitters and growth factors) which activate plasma membrane G-protein- as well as tyrosine kinase-coupled receptors. Some TRPs are directly activated by the stimuli, while others are activated by downstream signaling components that are generated in response to the stimuli. The TRP superfamily consists of seven subfamilies: TRPC (TRP-canonical), TRPV (TRP-vanilloid), TRPM (TRP-melastatin), TRPN (TRP-no mechanoreceptor potential C (NOMPC)) and TRPA (TRP-ankyrin), and two related channel types, TRPP (TRP-polycystin) and TRPML (TRP-mucolipin). This article discusses the major mammalian TRP channel subfamilies, TRPC, TRPV, and TRPM, with relatively more focus on the function and regulation of TRPC channels (Figure 1).

Major Features of TRP Channel Structure

TRPC channel subfamily consists of seven members, TRPC1–TRPC7 (TRPC2 is a pseudogene in humans), TRPV family of six members (TRPV1–TRPV6), while TRPM family has eight members (TRPM1–TRPM8). TRP channels were originally predicted to have six putative transmembrane (TM) domains with a pore domain between the fifth (S5) and sixth (S6) TMs. Channel topology was confirmed for several TRP channels and it has been suggested that, like other 6-TM channels, TRPs probably form a tetrameric quaternary structure, where each subunit contributes to the channel pore. Some TRP channels display voltage dependency in their gating. Furthermore, gating efficiency in many TRPs can be modulated by other factors, for example, temperature and pH exert simultaneous effects of

TRPV1 activity, while temperature and tastant together can affect TRPM5 activity. Amino acid sequences flanking the pore in TRP channels are most strongly conserved across the TRP channel family. S5, S6, and the proximal C-terminal tail (TRP domain) are strikingly similar even in disparate TRP channels. A homologous block of ~25 intracellular residues immediately C-terminal to S6 is loosely conserved in all TRP mammalian subfamilies except TRPA and TRPP and has been referred to as the TRP domain. This domain is composed of a highly conserved six-amino acid sequence (six amino acids (EWKFAR) in TRPC channels) as well as a proline-rich sequence. Recently, residues within the TRP domain were demonstrated to be required for PIP₂ binding and regulation of channel gating of TRPM8 and TRPV5 channels. However, phosphatidylinositol 4,5-bisphosphate (PIP₂) stimulates some TRP channels (TRPV5, TRPM5, TRPM7, and TRPM8) while inhibiting others (TRPV1). How exactly PIP₂ regulates these channels is not yet known. Ca²⁺ and calmodulin (CaM) also regulated a number of TRP channels. TRPCs and a number of other TRPs have one or more binding sites for CaM as well as Ca²⁺. These have been reported to be involved in activation, inactivation, as well as channel trafficking.

The TRPC and TRPV proteins contain three to four ankyrin repeats in their N-terminal domain as well as a coiled-coiled region. The former has been proposed to play a role in interaction of the channel with scaffolding and regulatory proteins, while the CC-domain might be involved in TRP channel multimerization. Consistent with the presence of putative protein-interacting domains, TRP channels are assembled in a multiprotein signaling complex. Importantly, some key Ca²⁺ signaling proteins are associated with TRPC channels, such as inositol trisphosphate receptor (IP3R), plasma membrane Ca²⁺ ATPase (PMCA), sarco/endoplasmic reticulum Ca²⁺-ATPase (SERCA), G proteins, phospholipase C (PLC), Homer, and Na(+)/H(+)-exchanger regulatory factor-1/Ezrin-radixin-moesin-binding phosphoprotein-50 (NHERF/EBP-50). The TRP-associated proteins range from scaffolding, to trafficking, and regulatory. In addition, putative protein kinase A (PKA), and C (PKC) phosphorylation sites, phosphatidylinositol 3-kinase (PI3K) and Src-homology-2 (SH2)-recognition domains (YXXM motifs) and putative PDZ interaction domains have also been identified in several TRPs. Further studies are

Figure 1 TRP channel structure and activation.

required to clearly understand the exact role of these domains and accessory proteins in channel function.

TRPV subfamily members share ~25% amino acid identity to other TRP proteins, mainly in the pore region. The localization of the pore loop has been confirmed by mutational analyses of residues within the pore for TRPV5 and TRPV6, TRPV1, and TRPV4. Recent studies demonstrate the importance of ANK repeats for the tetramerization of TRPV6 and TRPV5 ion channels; however, they could also mediate interaction of TRPVs with other proteins or the cytoskeleton. TRPV proteins display distinct modes of activation which result from the channel ability to respond to ambient and higher temperatures as well as osmolarity. The TRPV family has been subdivided on the basis of structure and function, TRPV1/TRPV2, TRPV3, TRPV4, and TRPV5/6. TRPV1, 2, 3, and 4 are modestly permeable for Ca^{2+} . TRPV5 and 6 are the only highly Ca^{2+} selective channels in the TRPV family. Like other TRPs, TRPVs are shown to have a number of proteins associated with them, including CaM. TRPV5 interacting protein, namely S100A10 (p11, calpactin light chain, or annexin 2 light chain), was identified. Both TRPV5 and TRPV6 contain a conserved binding site for S100A10 binding localized to the intracellular C-terminal region shortly downstream of the last TM domain (S6). Deletion of this PDZ binding motif within TRPV5 leads to greatly diminished surface expression and function.

The TRPM subfamily of ion channels comprises eight members divided into three main groups: TRPM1/3, TRPM4/5, and TRPM6/7, which regulate diverse cell functions, for example, taste detection, Mg^{2+} homeostasis, cell proliferation, and cold sensing. TRPM4 and TRPM5 are the only Ca^{2+} -impermeable TRP channels identified to date, while TRPM3, TRPM2, and

TRPM8 are Ca^{2+} -permeable cation channels with low Ca^{2+} selectivity. TRPM6 and TRPM7 are relatively highly permeable for divalent cations, including Mg^{2+} . The functional properties of TRPM1 have not been reliably characterized. TRPM channels possess low homology with other TRP subfamilies. All TRPM channels possess a TRPM-homology region which is not found in other known proteins. The biological significance of this region remains unknown. A feature unique to the TRPM family of ion channels is the presence of C-terminal enzymatic domains in three of its family members, TRPM2, TRPM6, and TRPM7. In addition, TRPM2 has a C-terminal domain with homology nucleoside diphosphate linked to X (NUDIX), an enzyme with adenosine diphosphate (ADP)-ribose hydrolase activity. TRPM6 and TRPM7 are not closely related to TRPM2 and are also enzymes, as both contain an eEF2 α -kinase family Ser/Thr kinase domain in their C-terminal region. The exact function of the enzyme domains in these channels is not yet known.

Activation of TRP Channels

Channel classification is not based on activation mechanisms but rather on sequence homology. Members of the TRPV and TRPM subfamilies are activated via temperature sensation, while mechanical or osmotic stimuli also activate some TRPVs. Some TRPs are constitutively active channels and are modulated via regulated trafficking. Other various activation mechanisms include activation of free radicals (TRPM2 and TRPC3), changes in $[\text{H}^{+}]$ (TRPVs), and changes in PIP_2 (implied for a number of TRP channels). Most similarity in

activation mechanisms is seen in the regulation of TRPCs, which are all activated in response to stimulation of PLC, which lead to PIP₂ hydrolysis. The notable feature of some TRP channels is their capacity to be activated by multiple modalities. Good examples of these are members of TRPV and TRPM subfamilies, although some TRPCs appear to display these properties as well.

The major mechanisms of activation of TRP channels can be summarized as follows:

1. *Receptor stimulation.* G-protein-coupled receptors (GPCRs) and receptor tyrosine kinases that activate PLCs can modulate TRP channel activity. This has been demonstrated extensively in the case of TRPCs. Some TRPCs (TRPC4 and TRPC5) appear to be regulated by PIP₂ *per se*, while others (TRPC3, TRPC6, and TRPC7) are activated by the hydrolysis product, diacyl glycerol, although the exact mechanism involved in this is not yet clear. TRPC1, TRPC3, and TRPC4 have also been reported to be activated via depletion of intracellular Ca²⁺ store.
2. *Ligand activation.* Ligands that regulate activation of TRP channels include small organic molecules, including synthetic compounds and natural products, endogenous lipids or products of lipid metabolism, purine nucleotides and their metabolites, or ions such as [Ca²⁺]_i, H⁺, and [Mg²⁺]_i.
3. *Direct activation.* Changes in ambient temperature are strongly coupled to the gating of TRPV1–TRPV3 and TRPM8. Other putative direct activators include mechanical and osmotic stimuli. Heating and cell swelling may also act indirectly to activate TRP channels through generation of second messengers (e.g., TRPV4 activation by hypotonic cell swelling is associated with the generation of arachidonic acid) or other as-yet-unidentified mechanisms.
4. *Constitutive activation.* Some TRPs display constitutive activation. These channels are regulated by trafficking or other mechanisms including protein kinases, Ca²⁺/CaM, as well direct effects of Ca²⁺ or Mg²⁺ (the latter suppresses TRPM7).

TRP Channel Function

Sensory Functions

TRPV, TRPM, TRPA subfamilies play critical roles in sensory modalities, such as touch, hearing, taste, olfaction, vision, and thermal sensation. A number of mammalian TRP channels are activated by temperature changes and play a key role in animal behavior and response to ambient temperature. TRPV1 and TRPV2 are sensors for very warm (>43 °C) and very hot (>52 °C) temperatures, respectively, whereas TRPV3 (>30–39 °C) and TRPV4 (~25–34 °C) contribute to sensing moderate temperatures. TRPM8 appears to function as a cold sensor. The role for TRPA1 in cold sensing is controversial. Most thermoTRPs are expressed in neurons involved in thermosensation. However, TRPV3 and TRPV4 are also expressed in keratinocytes and are activated by temperature increase in these cells. It has been proposed that keratinocytes might release adenosine triphosphate (ATP) that acts in an autocrine fashion to activate residing neurons in the skin. High-temperature sensing TRPs have also been shown to be involved in pain sensation and it is believed that the sensing mechanism at the channel level is similar in both cases.

Many TRP channels bind to and are regulated by various natural product ligands. For example, TRPV1 binds to capsaicin, a compound which elicits the sensation of heat. In addition to displaying impaired responses to heat and vanilloid compounds, TRPV1^{-/-} mice display minimal thermal hyperalgesia. On the other hand, TRPA1 accounts for response to chemical irritants, such as mustard oils, while TRPM5 is a taste transduction channel which broadly senses taste associated with sweet, bitter, and amino acids. Interestingly, TRPM5 contributes to the enhanced perception of sweetness at higher temperatures. TRPC2 functions in pheromone detection and response. Male mice lacking the channel fail to show the normal aggressive behavior toward intruding males.

Other sensory functions served by TRP channels include mechanosensation. TRPV4 is activated by hypotonicity, although it is not believed that the channel is directly activated by membrane stretch, rather arachidonic acid generated in response to osmotic stress might be the activator of the channel. However, TRPV4 serves a sensing function and is required for regulatory volume decrease.

Other Functions Served by TRP Channels

TRP channels play important roles in the secretion and absorption of fluids, electrolytes, and hormones in vertebrates and invertebrates. Further, they are involved in critical cellular processes such as embryonic development, neuronal growth, endothelial migration and proliferation, and cell volume regulation. Two TRPM channels have been suggested to be involved in insulin secretion, TRPM2 and TRPM4. TRPV1 is required for urinary bladder function and mutations in TRPV1 result in an increase in urinary bladder capacity and decreased voiding. The exact mechanism by which TRPV1 regulates urinary bladder function is not clear. There is definitive evidence that TRP channels are required for renal function. TRPV5 mutations are associated with abnormal renal function in humans. Deletion of TRPV5 in mouse causes hypercalciuria due to a defect in Ca²⁺ reabsorption through the distal convoluted tubule of the kidney, where TRPV5 is localized. TRPV5 is also expressed in osteoclasts and contributes to transcellular Ca²⁺ transport during osteoclastic bone resorption. TRPV5 and the highly related TRPV6 are the most Ca²⁺-selective channels among the mammalian TRPs and are involved in absorption of Ca²⁺ in epithelial tissues such as kidney and gut. TRPM7 appears to be involved in embryonic development likely by regulating growth factor-mediated signaling pathways. TRPC channel function and regulation are discussed below.

TRPC Channel Function

Based on amino acid similarities, the mammalian TRPCs can be grouped into four subgroups: TRPC1, TRPC2, TRPC3/6/7, and TRPC4/5. Some TRPCs (such as TRPC1) are expressed ubiquitously. TRPCs have been shown to assemble as both homomeric and heteromeric complexes. Heteromers can be formed by association of TRPC1 with TRPC4 and TRPC5. Likewise, the TRPC3/6/7 subfamily can form heteromers among themselves, although TRPC1/TRPC3 heteromeric channels have been reported. The properties of heteromers may be different from those of the homotetramers. However, presently

there is poor evidence for endogenous TRPC heteromers or the possible functional consequences of such channel diversity.

TRPCs contribute to changes in $[Ca^{2+}]_i$ by acting as Ca^{2+} entry channels in the plasma membrane directly or by changing the membrane potential which can modulate the driving force for other channels. TRPCs are basically nonselective Ca^{2+} -permeable cation channels with variable Ca^{2+}/Na^+ permeability ratios. In excitable cells, Na^+ entry through TRPC channels would lead to membrane depolarization, activation of voltage-gated Na^+ and Ca^{2+} channels, and additional Ca^{2+} entry. In nonexcitable cells, Na^+ entry through TRPCs would make membrane potential more positive, alter cell volume, and affect other Na^+ -dependent cellular processes. Such effects have been reported for TRPC3, TRPC4, and TRPC6. In both excitable and nonexcitable cells, the activation of TRPCs results in increases in intracellular Ca^{2+} concentrations ($[Ca^{2+}]_i$) and Ca^{2+} -induced signaling cascade. Below are listed some of the reported functions of TRPC channels.

In receptor and store-operated calcium entry

TRPC channels are activated downstream of PLC. Therefore, these channels were first suggested to be the channels underlying I_{CRAC} . However, this was ruled out based on patch-clamp experiments which revealed mammalian TRPCs are nonselective cation channels which conduct Na^+ and K^+ as well as Ca^{2+} in most cases; thus, the channels appear to be distinct from Ca^{2+} release-activated Ca^{2+} (CRAC) channels. A substantial body of work demonstrates that TRPCs (TRPC1, TRPC3, and TRPC4) can also contribute to store-operated Ca^{2+} entry (SOCE), at least in some cell types. These data primarily include studies where knockdown of TRPC expression resulted in a reduction in SOCE. However, there is also extensive literature indicating that some TRPC channels do not operate as store-regulated channels *per se* but contribute to SOCE via secondary mechanisms. Indeed, the TRPC3/TRPC6/TRPC7 subfamily channels are activated by the second-messenger diacylglycerol (DAG), a product of PLC-dependent hydrolysis of PIP_2 . In addition, recent studies demonstrate that TRPC4 and TRPC5 can be directly activated by Ca^{2+} and levels of PIP_2 . While TRPC1, TRPC3, and TRPC4 activation is less defined, increasing number of reports now suggest that TRPCs might be regulated by STIM1, the endoplasmic reticulum (ER) calcium sensor that regulates SOCE. The strongest data available in this regard are for TRPC1. It has been shown that TRPC1 interacts with stromal interaction molecule 1 (STIM1) following store depletion and that this interaction occurs in the periphery of the cell. Further, an important study demonstrated that TRPC1 is gated by STIM1 through electrostatic interactions between the polybasic domain of STIM1 and conserved aspartate residues in TRPCs, in this case TRPC1 and TRPC3. In fact, TRPC1 has been suggested to be the link that mediates STIM1-dependent regulation of other TRPC channels. According to this model, TRPCs that interact to form heteromeric channels with TRPC1 would also exhibit STIM1-dependent activation. Another intriguing observation that remains unqualified is that TRPC1 activation is dependent on the function of Orai1, the major CRAC channel component. This functional or direct coupling between Orai1 and TRPC channels remains to be elucidated. Together, these new findings suggest that TRPC channel

regulation is more complex than previously proposed and could involve several components and levels of regulation.

In neurons

TRPC channels play roles in neurite outgrowth and growth cone guidance in the developing nervous system. TRPC3 was suggested as a candidate for regulation of growth cone guidance by brain-derived neurotrophic factor (BDNF) because it is activated in the developing mammalian brain by BDNF which was subsequently supported by studies with knockdown of TRPC3 expression. TRPC5 is involved in neurite extension. TRPC channels also function postsynaptically in response to the activation of metabotropic receptors. For example, release of gamma-aminobutyric acid (GABA) from the dendrites was greatly reduced in TRPC4^{-/-} mice. In contrast, TRPC1 appears to underlie an excitatory postsynaptic current that is generated in response to metabotropic glutamate receptor stimulation in Purkinje cells.

In vascular endothelial and smooth muscle cells

TRP channels exert several different effects on vascular function, including endothelial permeability, responses to oxidative stress, myogenic tone, cellular proliferative activity, migration, and thermoregulation. TRPCs (including TRPC1, TRPC3, TRPC4, and TRPC6) act as SOC entry or receptor-operated calcium (ROC) entry channels and regulate vascular permeability. Influx of Ca^{2+} into vascular endothelial cells causes the release of vasoactive agents, which affect vascular smooth muscle. Although many TRP channels are expressed in the endothelium, the data are strongest for TRPC4. Mice lacking TRPC4 are deficient for an IP_3 -induced Ca^{2+} influx current and display greatly reduced vasorelaxation. In contrast, knockout of TRPC6 increases vascular smooth muscle contractility and blood pressure due to an increase in the expression of TRPC3, which has constitutive activity under these conditions. In addition, TRPC can have an important role in vascular proliferation and remodeling. TRPC6 plays an important role in vascular endothelial growth factor (VEGF)-mediated angiogenesis, while TRPC4 participates in vascular remodeling. Remodeling can be possibly regulated via two mechanisms: proliferative factors may activate TRP channels, with the consequent increase in intracellular Ca^{2+} , thus modulating the signal transduction pathways and leading to remodeling; second, Ca^{2+} influx through TRP channel may stimulate endothelial cells to produce and release proliferative factors such as VEGF and platelet-derived growth factor (PDGF), which then subsequently induce vascular remodeling.

In exocrine gland cells

Salivary secretion is Ca^{2+} dependent, and increases in $[Ca^{2+}]_i$ are associated with increased secretion. Adenovirus-mediated overexpression of human TRPC1 in rat submandibular glands results in a fivefold increase in muscarinic-stimulated fluid secretion and enhanced Ca^{2+} entry response to carbachol and thapsigargin. This was confirmed by studies with TRPC1^{-/-} mice which displayed severe loss muscarinic-stimulated salivary fluid secretion together with decreased agonist- and thapsigargin-stimulated Ca^{2+} entry. Similarly, TRPC3^{-/-} mice displayed reduced SOCE in pancreatic acinar cells, which was linked to a reduction in the severity of pancreatitis.

This suggests a possible involvement of TRPC3 in normal physiology as well as pathophysiology of the exocrine pancreas.

TRP Channels and Human Diseases

Given the diversity in the properties and regulation of TRP channels, it is not unexpected that they appear to have major roles in human disease. While in many cases the effect of alterations in TRP channel function or expression leads to downstream changes in cell signaling and function, several TRP channelopathies have been identified in which mutations in TRP channels have been shown to be causative in the disease. We will summarize these here.

TRPC channel genes have been linked to cardiovascular and pulmonary diseases, inflammation, cancer, skin diseases, neurological diseases, (diabetic) kidney diseases, and proliferative diseases via dysregulation of the cell cycle. The only TRPC-related channelopathy described so far is focal and segmental glomerulosclerosis (FSGS), which has been linked to TRPC6 mutation. FSGS is functionally characterized by proteinuria and progressive decline in renal function of the late-onset type. Since the TRPC6 mutations in FSGS patients are gain of function, it is suggested that enhanced Ca^{2+} entry through TRPC6 may constitute the pathogenic trigger that initiates cell death or compromises the permeability barrier. Activation of nuclear factor of activated T (NFAT) cells could also play an important role in FSGS.

TRPV channelopathies have been linked to skeletal dysplasias. Mutations in *Trpv4* cause a spectrum of skeletal dysplasias, which are lethal in some cases. Spondylometaphyseal dysplasia (SMD) Kozlowski type (SMDK) has been linked to missense mutations in *Trpv4*. These mutations lead to alterations in the basal activity of TRPV4 channels. Scapuloperoneal spinal muscular atrophy (SPSMA) and Charcot-Marie-Tooth disease type 2C (CMT2C; also known as hereditary motor and sensory neuropathy type 2) are phenotypically heterogeneous neurodegenerative disorders in which function of TRPV4 might be anticipated. Four TRPV4 mutations have been identified in this case although how these impair the TRPV4 function is not yet known.

TRPM1, or melastatin, is a putative tumor suppressor protein in melanoma cells. TRPM1 expression decreases in melanoma cells, resulting in progression of malignant melanoma. More recently, around 14 mutations in the *Trpm1* gene are linked to autosomal recessive congenital stationary night blindness (CSNB), a clinically and genetically heterogeneous group of retinal disorders characterized by nonprogressive impaired night vision and variable decreased visual acuity. All patients with recessive *Trpm1* mutations display myopia, reduced central vision, nystagmus, and electroretinographic (ERG) evidence of ON bipolar cell dysfunction. Mutations in *Trpm2* and *Trpm7* genes cause Guamanian amyotrophic lateral sclerosis (ALS-G) and parkinsonism-associated dementia (PDC), as a result two related neurodegenerative disorders. Further, both TRPM2 and TRPM7 are directly implicated in neuronal cell death pathways by sensing oxidative stress (TRPM2) and being crucial for cell viability in neurodegenerative diseases, including Alzheimer's disease and amyotrophic lateral sclerosis. Indeed, a subset of ALS-G and PDC are

heterozygotes for a missense mutation in the *Trpm2* and *Trpm7* genes.

TRPM6, like TRPM7, is involved in Mg^{2+} homeostasis. Mutations in *Trpm6* gene have been associated with hypomagnesemia with secondary hypocalcaemia (HSH) or HOMG. HSH is an autosomal recessive disorder that is characterized by very low Mg^{2+} and Ca^{2+} levels in the serum. This disease is diagnosed during the first 6 months of life due to characteristic neurological symptoms. The primary defect in HSH is an impaired intestinal Mg^{2+} reabsorption. A decreased renal/intestinal Mg^{2+} reabsorption and the resulting decrease in serum Mg^{2+} levels seem to lower parathyroid hormone (PTH) output by the parathyroid gland. A decrease of both PTH and serum Ca^{2+} levels (secondary hypocalcemia) results in convulsions and spasms in early infancy that, if left untreated, can lead to mental retardations or death.

A mutation in the *Trpm4* gene causes autosomal dominant progressive familial heart block type I, a progressive cardiac bundle branch disease in the His-Purkinje system. This has been associated with deSUMOylation of the channel, impairing its endocytosis, thus leading to the elevated channel density in the plasma membrane. The increase in plasma membrane TRPM4 channel very likely causes depolarization of the conduction system and the heart block.

Conclusion

Since their identification almost a decade ago, TRP channels have emerged as regulators of diverse and critical cellular and physiological functions. In addition to those discussed in this chapter, TRP channels are expressed and function in a great variety of multicellular organisms, including worms, fruit flies, zebrafish, and even yeast, indicating a strong evolutionary significance in these channels. Most importantly, based on the wide range of cellular functions performed by mammalian TRP channels, these channels appear to be involved from most basic to highly specialized cellular processes. Further, impact of disruption of channel function has now been associated with the progression of disease and in some instances established as the causative factor in the disease process. Therefore, TRP channels are exciting targets for drug development for the control of pain, asthma, and neurodegenerative diseases. Future studies hold exciting new prospects for further understanding the function and regulation of these remarkable versatile cation channels.

Glossary

Aminoacyl-tRNA tRNA enzymatically esterified with an amino acid at its 3'-CCA end.

Codon The three nucleotide units of information within mRNA that is recognized by the anticodon of transfer RNA molecules on the ribosome to bring specific amino acids into the ribosome.

Decoding center/decoding site The region of the small subunit of the ribosome responsible for recognizing shape-specific features of the tRNA anticodon-mRNA codon minihelix during tRNA selection.

Elongation factor-G (EF-G) The conserved protein molecule responsible for catalyzing the process of directional substrate translocation on the ribosome during the elongation phase of protein synthesis. Also responsible for aspects of the ribosome recycling mechanism.

Elongation factor-Ts The protein molecule responsible for catalyzing nucleotide release from EF-Tu; EF-Ts is a guanosine nucleotide exchange factor (GEF).

Elongation factor-Tu (EF-Tu) The conserved protein molecule responsible for escorting tRNA substrates into the A site of the ribosome during the elongation phase of protein synthesis.

GTPase activating center (GAC) The site within the large subunit of the ribosome responsible for specific interactions with translation factors that triggers GTP hydrolysis.

Guanosine diphosphate (GDP) One of the small-molecule by-products of GTP hydrolysis.

Guanosine triphosphate (GTP) A small molecule that serves as the energy source for multiple translation reactions.

Messenger RNA (mRNA) Ribonucleic acid template molecules read by the ribosome in a directional fashion to synthesize specific protein products.

Peptidyltransferase center (PTC) The site within the large subunit of the ribosome responsible for catalyzing peptide bond formation.

Ribosome The enzyme responsible for carrying out protein synthesis in the cell.

Ribozyme A structured molecule composed of ribonucleic acid that is capable of catalyzing specific chemical reactions.

Transfer RNA (tRNA) The substrate of the ribosome, a 25 000 Da, L-shaped adapter molecule composed of ribonucleic acid that brings specific amino acids to the translating particle through base-pairing interactions with the mRNA codon sequence.

Translocation The directional movement of tRNA and mRNA substrates with respect to the ribosome.

tRNA selection The process by which specific aminoacyl-tRNA molecules are selected by the ribosome according to the mRNA codon sequence.

Introduction

The 'central dogma of molecular biology' proposed by Francis Crick in 1958 specifies that genetic information within cells flows from DNA to RNA and then to protein. This process of information transfer is carried out by two, highly conserved macromolecular assemblies, whose regulation is central to the gene expression mechanism.

Transcription, carried out by RNA polymerase, converts double-stranded, chromosomal DNA into single-stranded messenger RNA (mRNA). Translation, carried out by the ribosome, converts the triplet codon sequence of mRNA into a specific polypeptide. Both RNA polymerase and the ribosome serve as integration points for the regulation of gene expression in the cell. The balance of these enzymes' synthesis activities and the various degradation activities in the cell responsible for mRNA and protein turnover give rise to the transcriptome and the proteome, respectively.

While RNA polymerase and the ribosome are physically distinct macromolecular assemblies, the paradigms of transcriptional and translational control are in many ways analogous. Both enzymes are directed to: (1) localize to an appropriate start site of synthesis on a structured nucleic acid template; (2) processively synthesize product by unwinding and transiting

the template strand in discrete steps by pairing individual substrate molecules with the segments of the template strand – the process of elongation; and (3) correctly terminate synthesis upon completion of a full-length product, and not before.

Although it is generally accepted that transcription and translation are principally regulated by controlling initiation, it is increasingly clear that the synthesis phases of both processes serve as important points of control in the gene expression mechanism. Mechanisms that enable control of these molecular machines allow cells to respond to intra- and extracellular queues through changes in the repertoire of mRNAs and proteins that are synthesized. The capacity to promptly regulate active synthesis reactions likely enables cells to respond rapidly to environmental queues and to diversify the nature and spatial distribution of the proteome in ways that are advantageous to cell growth. This chapter focuses on the synthesis phase of translation catalyzed by the ribosome, the elongation phase of protein synthesis.

Bacterial Ribosome Assembly

The bacterial ribosome is a massive ribonucleoprotein (RNA-protein) complex (approximately 2.5 MDa) composed of

distinct gene products, including three RNA molecules and 57 proteins. Ribosome biogenesis occurs in a region within the cell nucleus called the nucleolus. This complex, multistep process is driven by transcription of the conserved ribosome DNA operon by RNA polymerase I. Assembly of the ribosome commences on the nascent ribosomal RNA (rRNA) transcript through a relatively slow process involving a battery of enzymes including chaperones, helicases, and RNAases as well as factors that post-transcriptionally modify the rRNA. Actively growing laboratory strains of bacteria divide in 30–60 min and contain approximately 10 000–20 000 ribosomes. Given steady-state conditions, the rate of ribosome biogenesis can therefore be estimated at roughly 250 ribosomes per minute. To meet such demands, most rapidly dividing strains of bacteria typically contain duplicated copies of the conserved rRNA operon.

The assembled and fully processed ribosome is a two-subunit RNA–protein enzyme. In bacteria, the individual subunits are commonly referred to as 30S and 50S particles, which correspond to their sedimentation velocities. Each subunit is composed of approximately 35% protein and 65% rRNA, the latter of which contains approximately 5–10 unique posttranscriptional modifications whose precise function remains unclear. The locations of modified nucleotides within functional centers of the large and small subunit rRNA suggest some degree of contribution to core functions of the ribosome during translation.

Bacterial Ribosome Composition

The small, 30S, subunit contains a single RNA molecule of approximately 1500 nucleotides (16S rRNA) and 21 proteins. The large, 50S, subunit contains two RNA molecules totaling approximately 3000 nucleotides (~120 of 5S rRNA and ~2900 of 23S rRNA) as well as approximately 36 proteins. While the functional ribosome is an amalgam of both large and small subunits, a 70S particle in bacteria, biochemical studies have attributed distinct and separable activities to each subunit.

The small subunit is principally responsible for interactions with the mRNA template, which encodes the instructions for which protein to synthesize, as well as interactions with the anticodon stem-loop regions of ribosome-associated tRNA molecules. The site where mRNA codon–tRNA anticodon interactions are formed is referred to as the decoding site.

The large ribosomal subunit is responsible for the catalysis of peptide bond formation, an enzymatic activity that covalently links amino acids carried by adjacently bound tRNA substrates into a polypeptide chain. Peptide bond formation on the large subunit occurs within the peptidyltransferase center (PTC). This site contains two highly conserved rRNA elements which form base-pairing interactions with the universally conserved 3′-CCA ends located at the tips of the acceptor stem region of tRNA molecules. The large subunit also contains the GTPase activating center (GAC) that triggers GTP hydrolysis within the ribosome-associated translation factors including elongation factors (EF)-Tu and (EF)-G, initiation factor (IF)-2, as well as release factor (RF)-3.

Bacterial Ribosome Architecture

Following the identification of the ribosome as the site of protein synthesis within the cell in the mid- to late 1950s – an achievement that contributed to the Nobel prize in physiology and medicine awarded to Albert Claude, Christian de Duve, and George Emil Palade – attempts to characterize its physical makeup and structure quickly ensued. Negative stain electron microscopy, immunoelectron microscopy, and cryoelectron microscopy made many early contributions in the area, including the first overall topological maps of the 70S particle. The critical roles electron microscopy played over the years include, among other things, the anthropomorphized nomenclature used to describe the various structural features of the small and large subunits (discussed below).

Cryoelectron microscopy methods continue to have an enormous impact on the translation field to this day by providing structural snapshots of the changing ribosome architecture during initiation and synthesis reactions. Such achievements have served as an important starting point for atomic resolution structure determination efforts.

The first atomic resolution structures of the ribosomal subunits, revealed in 2000, culminated more than three decades of previous structural, biochemical, and genetic research into the mechanism of translation ([Figure 1\(a\)](#)). Three of the pioneers in this area, whose labs contributed to making these breakthroughs possible, were awarded the Nobel prize in chemistry in 2009: Drs. Ada Yonath, Venkatraman (Venki) Ramakrishnan, and Thomas Steitz. The efforts of these scientists capitalized on widely recognized contributions of many other leaders within the field.

The large, 50S, subunit is roughly globular in nature, and approximately 250 Å in diameter, but contains three stalk-like protrusions called the L1 stalk, the L12 stalk, and the central protuberance that extend away from the particle's core. In the crown view orientation of the ribosome, the L1 and L12 stalks – so called because they contain the ribosomal proteins L1 and L12 – extend away from the large subunit core and its central protuberance toward the lagging and leading edges of the particle, respectively. The highly compacted core of the 50S particle is principally composed of 23S rRNA. Ribosomal proteins distribute evenly throughout the subunit such that their globular domains are positioned near the solvent-exposed surfaces. Long, positively charged, C- and N-terminal extensions penetrate deep into the core to stabilize tertiary interactions between 23S rRNA segments. The site responsible for peptide bond formation, the PTC, is located near the center of the 50S particle. The unusual resistance of PTC activities to protease digestion and extraction procedures, combined with structural data revealing that it is principally composed of RNA, has led most to conclude that the ribosome is a ribozyme.

The 30S subunit is relatively flat (approximately 250 Å long, 50 Å thick, and 180 Å wide) and flexible by comparison. The small subunit is composed of three, roughly globular domains, referred to as the head, body, and platform, that are connected by a narrow neck-like extension composed of 16S rRNA. mRNA binds at the interface of these three domains, encircling this neck element. In so doing, the small subunit holds a segment of approximately 18 nucleotides – six tandem mRNA

Figure 1 Structures of the 30S and 50S ribosomal subunits as well as the functionally active 70S particle. Distinct views of three-dimensional, atomic models of the bacterial ribosome. (a) The large (50S) and small (30S) subunits of the bacterial ribosome shown in crown view with landmark structural features indicated. Ribosomal proteins are shown in blue and tan in the large and small subunit, respectively; in both subunits, rRNA is shown in gray ribbons. (b) The 70S pre-translocation ribosome complex shown in a cross-section view (as indicated) looking down the subunit interface to reveal the tRNA substrate-binding channel comprising the A, P, and E sites where A- and P-site tRNAs are shown in their classical positions (red). Landmark structural features, including the decoding site (DS), the peptidyltransferase center (PTC), L1 stalk, L12 stalk, the GTPase activating center (GAC), the A-site finger (ASF), and mRNA track are indicated (PDB accession codes 2QAL, 2QAM, 1VS9, and 1Q86).

codons –exposed to the solvent so as to facilitate its interactions with tRNA substrates.

The translationally active, 70S particle, is formed by the joining of large and small subunits through a relatively flat, RNA-rich interface such that the head and central protuberance domains of the small and large subunit juxtapose. High-resolution structures of the 70S particle, emerging as early as 2005 from the group of Dr. Harry Noller and colleagues, provided the first molecular insights into the RNA–RNA and RNA–protein bridges mediating 70S complex formation. Later studies, including work from the groups of Noller, Yusupov, Ramakrishnan, and Cate, further contributed to revealing the molecular basis of the three tRNA-binding sites within the 70S particle. These sites are commonly referred to as the aminoacyl (A), peptidyl (P), and exit (E) sites based on their preferred binding of aminoacyl, peptidyl, and deacylated tRNA, respectively.

tRNA substrates orient within a solvent-exposed channel running the length of the 70S particle in a manner that is roughly perpendicular to the subunit interface. In so doing, the L-shaped, 25 kDa tRNA molecules are positioned such that their anticodon domains can form Watson–Crick base-pairing interactions with mRNA on the small subunit while

their acceptor stem, and single-stranded 3′-CCA residues can interact with conserved elements within the large subunit PTC (Figure 1(b)).

The Mechanism of Bacterial Protein Synthesis

In both prokaryotic and eukaryotic systems, the process of protein synthesis by the ribosome is carried out in four principal stages: initiation, elongation, termination, and recycling (Figure 2). Many key mechanistic considerations for the process of translation are conserved among species, including the size, structure, and functional contributions of each of the translation components. Although initiation is generally considered the rate-determining step in translation, each phase can be exquisitely regulated in the cell through changes in the cellular milieu and/or changes in the composition of the translation machinery.

Initiation

Initiation localizes the large and small subunits of the ribosome, along with a specialized, *N*-formylmethionine-charged

Figure 2 Schematic representation of the four principal phases of translation. This highly simplified diagram illustrates initiation, elongation, termination, and recycling steps, as well as the translation factors responsible for facilitating these reactions.

initiator tRNA substrate ($fMet-tRNA^{fMet}$) to the start site of protein synthesis. This site is typically located within the 5'-end of the mRNA template. As elaborated elsewhere in this edition, the initiation process entails a two-dimensional scan of the mRNA sequence, wherein the ribosome, aided by IFs and GTP hydrolysis, pairs initiator tRNA with the start codon, typically an AUG sequence. Start-site selection establishes the reading frame of protein synthesis and is therefore a key determinant of overall translational fidelity. The use of alternative cryptic start sites increases the diversity of protein products from a single mRNA transcript. Completion of the initiation process results in a post-initiation ribosomal complex in which the subunits are joined and $fMet-tRNA^{fMet}$ binds to the mRNA start codon within the P site of the ribosome. In this complex, the universally conserved, 3'-CCA end of the $tRNA^{fMet}$ acceptor stem forms two Watson-Crick base pairs with the P loop of

23S rRNA, a conserved RNA element within the large subunit PTC. Concurrently, the $tRNA^{fMet}$ anticodon stem loop forms three Watson-Crick base pairs with the mRNA codon within the small subunit-decoding region. Once the formation of this complex is complete, the elongation phase of protein synthesis begins.

Elongation, the Synthesis Phase of Translation

During the elongation phase of protein synthesis, the ribosome translates the mRNA open reading frame (ORF) into protein by pairing specific aminoacylated-tRNA molecules ($aa-tRNA$) with the mRNA codon sequence. There are 44 distinct tRNA genes in the bacterial genome. Each species of tRNA in the cell is enzymatically charged with one of the 20 essential amino acids through the action of a diverse family of proteins

collectively referred to as aminoacyl-tRNA synthetases (aaRSs). The charging of tRNA is an ATP-dependent reaction resulting in the covalent linkage of the carboxylic acid moiety of an amino acid to the terminal 2' or 3' hydroxyl group of the universally conserved 3'-CCA sequence within the tRNA acceptor stem, forming a labile ester bond between the tRNA and amino acid. The specificity of aminoacylation, determined by identity elements within each tRNA molecule, is a critical determinant of translational fidelity. The overall fidelity of tRNA aminoacylation (approximately 1 error in 10^6 – 10^7) is ensured by proofreading mechanisms within specific aaRS proteins, wherein the ester linkage of incorrectly charged tRNAs is specifically hydrolyzed. Each of the 44 aa-tRNA substrates is used by the ribosome to decode one or more of the 61 sense codons. The remaining three mRNA codons are called nonsense codons, which instruct the ribosome to terminate protein synthesis. Nonsense codons are specifically recognized by protein factors that release the synthesized protein from the ribosome by water-catalyzed hydrolysis of the tRNA–amino acid ester linkage.

Elongation, the protein synthesis phase of translation, is driven by repetitive cycles of aa-tRNA selection, peptide bond formation, and the directional translocation of tRNA and mRNA substrates. As detailed below, such processes are dominated by tRNA and factor-binding events at the leading edge of the translating particle mediated by ribosomal stalk protein L12 of the large subunit and factor-catalyzed GTP hydrolysis on the ribosome. The mechanism of elongation and the origins of fidelity in this complex process have received much attention over the past several decades by many research teams. Current models of aa-tRNA selection and translocation stem principally from rapid stopped-flow fluorescence and quenched-flow measurements pioneered by the groups of Wintermeyer, Rodnina, and colleagues, which have been later supplemented by bulk and single-molecule fluorescence and fluorescence resonance energy transfer measurements. Aminoacyl-tRNA molecules are selected at the A site of the ribosome, located at the leading edge of the 70S particle, according to the mRNA template sequence through a multistep, kinetically driven mechanism.

Unlike other processive enzymes in the cell, such as DNA polymerase, the ribosome lacks the capacity to proofread mistakes after the process of substrate selection is complete. Thus, the mechanism of tRNA selection is critical in maintaining the genetic code, the observed correspondence between the mRNA ORF and protein sequence. As for initiation, the process of aa-tRNA selection is driven by Watson–Crick base-pairing interactions between the tRNA anticodon and the mRNA codon and is a key determinant of translational fidelity. The observed fidelity of aa-tRNA selection, estimated through a variety of both *in vivo* and *in vitro* measurements, as 1 error in 10^2 – 10^4 codons, ensures approximately one mistake per protein synthesized or less. Consistent with a careful balance of thermodynamic and kinetic driving forces in the tRNA selection mechanism, both experimental and theoretical evidence suggest that higher fidelity in this process can be achieved at the expense of slower rates of synthesis.

Although the process of tRNA selection is driven by the base pairing between the mRNA codon and tRNA anticodon, the observed fidelity of aa-tRNA selection far exceeds that which can be achieved on the basis of thermodynamic

considerations. Differences in the base-pairing stabilities of correct (cognate) and incorrect (near- and noncognate) aa-tRNAs with the mRNA codon – in some cases as little as a single hydrogen bond – may provide up to one to two orders of magnitude of selectivity, one to two orders of magnitude below what is empirically observed. Research into the origins of fidelity during selection has revealed that selectivity is rooted in the multistep nature of the process. EF-Tu, the conserved GTPase that binds the acceptor stem of aa-tRNA with high affinity, also contributes to the fidelity mechanism. GTP hydrolysis by EF-Tu occurs on the ribosome during the selection process, through a mechanism that is allosterically regulated by the nature of the mRNA codon–tRNA anticodon interaction. Rapid and efficient GTP hydrolysis selectively occurs when the correct, cognate tRNA is recognized through shape-selective elements of the small subunit of the ribosome. Insights into the allosteric GTP hydrolysis triggering mechanism were revealed first through genetic studies and later through structural investigations beginning with cryoelectron microscopy studies led by the Frank and Spahn groups and subsequently by X-ray crystallographic studies out of the Ramakrishnan lab. Such efforts suggest that structural distortions in the entering tRNA molecule as well as EF-Tu are precipitated by conformational changes in the small subunit that occur upon codon–anticodon recognition. tRNA bending and EF-Tu contacts with both large and small subunits participate in the GTP hydrolysis mechanism by allowing the catalytic histidine in EF-Tu to activate water for in-line attack of the gamma-phosphate of GTP. Subsequent release of inorganic phosphate and dissociation of EF-Tu(GDP) from the ribosome allows the aminoacylated, 3'-CCA end of tRNA to enter the PTC and participate in peptide bond formation. Following peptide bond formation, the nascent peptide is covalently linked to tRNA residing in the A site, a complex that is competent for EF-G-catalyzed translocation.

EF-G specifically recognizes the pre-translocation ribosome and operates through a GTP-dependent mechanism to drive the directional movement of tRNA and mRNA substrates with respect to the ribosome. Fidelity during this step relates to the precision with which substrate translocation occurs. In order to maintain the proper reading frame of translation, the ribosome must move with respect to the mRNA by a single codon during translocation. Movement by a nonintegral number of codons compromises the reading frame. Programmed mis-translocation events, including +1 and –1 frameshifting, have been shown to play important roles in the regulation of both housekeeping genes as well as the translation of viral genomes.

Although still an open area of research, EF-G's recognition of the pre-translocation complex is thought to be enabled by a number of specific conformational changes within the ribosome and related movements of 3'-CCA ends of both A- and P-site tRNA with respect to the large subunit. Such processes include a global motion of the small subunit with respect to the large, orthogonal swivel-like motions of the small subunit head domain in the direction of translocation and rearrangements of the A-site finger (ASF), an element of rRNA within the small subunit that lies above and between the A- and P-site tRNA-binding sites. These structural processes facilitate the formation of so-called, hybrid tRNA configurations that allow EF-G to engage the large subunit GAC to catalyze GTP hydrolysis and enter the A site of the small subunit. The formation of

hybrid pre-translocation complex configurations, and their role in the translocation mechanism, has been extensively investigated. Consistent with the notion that the ribosome possesses multiple conformational degrees of freedom, and that the tRNA molecule itself is flexible in nature, numerous hybrid pre-complex configurations likely exist. Thus far, two distinct hybrid configurations of the pre-translocation complex have been rigorously characterized through biophysical and structural means.

While much remains to be delineated about the nature of hybrid pre-translocation complex configurations and their role in subsequent substrate movement (translocation) at a molecular level, the preponderance of evidence suggests that dynamic processes within the pre-translocation complex play a critical role in the translocation mechanism. Current mechanistic models of translocation suggest that EF-G cannot productively engage the ribosome until it spontaneously achieves a configuration in which both A- and P-site tRNAs have adopted hybrid positions, wherein their 3'-CCA ends partially translocate with respect to the large subunit. Of course, such movements are associated with related conformational changes within the ribosome itself. Conformational changes within EF-G, facilitated by GTP hydrolysis, are also likely to play a central role in the translocation mechanism. Such changes are also thought to contribute to the factor's release from the ribosome, preparing the particle for additional elongation steps. Repetitive cycles of tRNA selection and translocation drive the ribosome directionally through the mRNA ORF sequence from the point of translation initiation to termination. In each elongation cycle, the nascent polypeptide is extended by a single amino acid.

Termination and Recycling Complete the Process of Protein Synthesis

When the ribosome reaches a nonsense mRNA codon, one that does not have a cognate tRNA pair, a release factor (either RF-1 or RF-2 depending on the specific stop codon encountered) binds to the A site. Release factor binding enables water to enter the PTC to hydrolyze the mRNA-encoded polypeptide from P-site tRNA, liberating it from the translating particle. A third factor, RF-3, acts to release the bound RF-1 or RF-2 through a process that requires GTP hydrolysis. Ribosomal subunits, tRNA and mRNA, are then separated from each other and prepared for subsequent translation reactions through the action of EF-G and ribosome recycling factor (RRF). Like other translation processes, recycling is mediated by conformational changes in the ribosome as well as energy expenditure. Efficient recycling ensures that the ribosome does not inappropriately reinitiate on downstream ORFs to complete the process of protein synthesis.

Fidelity and Regulation of Translation during Elongation Reactions

As described in previous sections, the elongation phase of protein synthesis serves as a critical determinant of the rate and fidelity of protein synthesis. Correspondingly, regulation of elongation reactions can have a dramatic impact on gene expression and the physical composition of the proteome.

Mechanisms that enable specific control of translation elongation reactions may provide a means to rapidly start or stop the synthesis of specific proteins, or modify the nature of the expressed protein. Known examples of such regulation include programmed alterations of translation elongation *via* the formation of thermodynamically stable secondary structures within the mRNA template. These can either halt the ribosome's transit through the mRNA ORF or induce frameshifting events that alter the reading frame and thus the protein product synthesized.

Examples of global translation elongation regulation are well documented. Such events include the stringent response, triggered by metabolite starvation, resulting in an overabundance of uncharged tRNA molecules that can bind the A site of the translating ribosome. Cells possess the means to detect such events – putatively through the binding of specific factors to the ribosome – resulting in the generation of small-molecule signaling compounds which downregulate ribosome biogenesis and the components of protein synthesis while simultaneously upregulating pathways for metabolite scavenging and synthesis.

The process of translation elongation can also be regulated by controlling the process of nucleotide exchange on EF-Tu. This reaction, catalyzed by elongation factor-Ts (EF-Ts), enables EF-Tu to release GDP after dissociating from the ribosome following the completion of tRNA selection, readying EF-Tu to again bind GTP and aa-tRNA. The activities of EF-Ts, a so-called guanosine nucleotide exchange factor (GEF), are essential to the cell as EF-Tu in its GDP-bound form is unable to bind aa-tRNA. EF-Tu also has an approximately 500-fold higher affinity for GDP than GTP. EF-Ts can be regulated by any number of means including protein–protein interactions that sequester and inactivate it, proteolysis, or post-translational modification.

Elongation reactions can also be regulated by the binding of small-molecule compounds to the translating ribosome. The most dramatic and widely understood examples of this means of control relate to antibiotic agents that are used in research and in the clinic to attenuate the process of translation. According to some estimates, roughly 40–50% of all known antibiotic compounds bind directly to the ribosome. Most of these compounds modify translation elongation reactions in some manner – some act as competitive inhibitors, others block specific conformational events required for proper elongation steps, while some actually promote steps that cause the ribosome to make errors in either tRNA selection, translocation, or termination. These latter compounds have the propensity to specifically or nonspecifically alter the proteome. It is not yet clear whether similar strategies are used by cells to control the gene expression mechanism in some specific manner. The capacity to alter ribosome function through the binding of chemically diverse small-molecule compounds, through both direct and allosteric mechanisms, portends many future discoveries that will shed light on new regulation mechanisms important for gene expression.

Conclusion

Our capacity to measure and quantify mRNA translation using new technologies will be critical to expanding the scope and

breadth of insights into translational control. Here, an emphasis on delineating the precise relationship between the expressed transcriptome and the proteome with increasing sensitivity is paramount. Today, there is no adequate way to do so. The recent emergence of ribosome profiling as well as single-molecule techniques that allow ribosome position on an mRNA to be directly monitored promise to make important contributions in this area that are sure to strengthen our understanding and expand our knowledge of the nature of gene expression mechanisms and the true complexity of bacterial and human proteomes.

Glossary

Aminoacyl-tRNA site (A-site) The binding site on the ribosome occupied by the tRNA carrying the next amino acid to be added to a growing polypeptide chain.

Peptidyl-tRNA site (P-site) The binding site on a ribosome occupied by the tRNA carrying a growing peptide chain.

Watson–Crick base pairing Association of two complementary nucleotides in a DNA or RNA molecule stabilized by hydrogen bonding between their base components.

Wobbling interaction Ability of a tRNA to recognize more than one codon by unusual (non-G-C, non-A-U) pairing with the third base of a codon.

Properties, Aminoacylation, and Formylation of the Initiator Transfer RNA

In bacteria, protein synthesis begins with a special brand of transfer RNA (tRNA), the initiator tRNA^{fMet}. Apart from being recognized by the same Met-tRNA synthetase as the elongator tRNA^{met} (the main recognition element being the CAU anticodon), the initiator tRNA is endowed with a number of structural and functional properties which make this particular RNA one of a kind. The main features distinguishing the initiator tRNA from elongator tRNAs are the three consecutive G–C pairs in its anticodon stem, which favor its interaction with the ribosomal P-site, the purine 11–pyrimidine 24 base pairing in the D-stem and the unpaired bases 1 (the 5′-end) and 72 which allow the recognition of Met-tRNA^{fMet} by the transformylase. It should be noted, however, that mutants lacking the transformylase are viable, albeit displaying a highly reduced growth rate. The initiation factor-2 (IF2)–fMet-tRNA interaction requires just a few bases of the 3′ acceptor end of the molecule. The fMet-tRNA is recognized by initiation factor IF2 by virtue of the chemical nature of the methionine, and largely relies on the presence of a formyl group blocking the α-NH₂ group of the amino acid. Indeed, fMet-ACCAAC has almost the same affinity for IF2 as the intact fMet-tRNA. IF2 can form a complex with fMet-tRNA off the ribosome but it has been demonstrated that this complex is nonproductive and that fMet-tRNA is recruited by ribosome-bound IF2.

The Translation Initiation Region of Prokaryotic Messenger RNAs

In bacteria, there are essentially three types of messenger RNAs (mRNAs) that are present in different proportions in different types of bacteria: (1) leadered with Shine–Dalgarno (SD) sequence; (2) leadered without SD sequence; and (3) leaderless (Figure 1). The most-studied and better-known mRNAs are those whose translation initiation region (TIR) contains, upstream of the initiation triplet, a 5′ untranslated region (5′ UTR) of variable length and structure, which generally includes a purine-rich SD sequence complementary to the

anti-SD sequence at the 3′-end of 16S ribosomal RNA (rRNA). The SD sequence and the initiation triplet are separated by a spacer of variable length (typically 5–9 non-structurogenic nucleotides). Also, the sequence at the 3′ side of the initiation triplet, the downstream region (DR), can have an influence on translational efficiency. Highly expressed mRNAs seem to have a bias in favor of an AAA triplet as the second codon and a CA repeat sequence within the first 15 codons was also shown to contribute to highly efficient initiation (Figure 1(a)). Both second and third types of mRNA do not contain the SD sequence either because this is not found in the 5′UTR leader (Figure 1(b)) or because the mRNA does not contain any 5′UTR and begins with the initiation triplet at their 5′-end (Figure 1(c)).

Concerning the initiation triplet, this is the codon from which the ribosomes begin to translate and which sets, at least provisionally, the reading frame of the template (a reading frameshift may occur during elongation). Aside from the leaderless mRNAs, which always begin with an AUG triplet, the other mRNAs may have different initiation triplets. In fact, whereas the most frequently used initiation triplet is AUG, ~10% of the templates begin with rarer yet canonical codons such as GUG and UUG, and, even less frequently, with noncanonical triplets such as AUU, AUC, and AUA. However, regardless of its nature, the initiation triplet is always decoded by the initiator fMet-tRNA. The reason for this initiation codon degeneracy is not always clear, but two facts should be recalled. First, AUG is the only triplet giving rise to a best-fit Watson–Crick base pairing with the anticodon (CAU) of the initiator tRNA, while all other start codons are expected to yield either 3′ or 5′ wobbling interactions with the same anticodon. Second, if not resulting from neutral mutations, the rare initiation triplets must be considered (or suspected to be) important regulatory signals capable of controlling timing and/or efficiency of translation. It is not by chance that, as described below, initiation factor IF3 can discriminate against translation beginning at noncanonical start codons; the best-known example of translation regulation based on the use of a rare codon is the translational auto-repression of IF3 mRNA which begins with an AUU initiation codon.

An important element that contributes to the efficiency of translation initiation is the secondary and tertiary RNA

Figure 1 Schematic representation of the features characterizing the translation initiation region (TIR) of bacterial mRNAs. (a) Leadered, SD-containing mRNA. The arrows indicate the beginning of the coding region with three of the most common initiation triplets. To the left of the start point is the 5' untranslated region (5' UTR) with the approximate location of the Shine–Dalgarno sequence (SD) whose theoretically most extended consensus sequence is indicated below. To the right of the start point is the 3' downstream region (3'DR) with the most favorable second codon AAA and the repeated CA dinucleotides acting as translational enhancers in some mRNAs. (b) Leadered, SD-lacking mRNA. The characteristics of the mRNA are the same as those described above but for the absence of the SD sequence in the 5'UTR. (c) Leaderless mRNA. Leaderless mRNA completely lacks the 5'UTR and begins obligatorily with a pAUG initiation codon.

structure of the TIRs, which may favor or disfavor formation of the 30S initiation complex and very often may influence mRNA stability. In general, mRNAs, whose TIRs are devoid of secondary structure, tend to be translated with greater efficiency, although it is the optimal combination of all the aforementioned TIR elements that can maximize translation of mRNA.

Initiation Complex Formation

Aside from the leaderless mRNAs, whose translation is believed to start with monomeric 70S ribosomes, the translation of all other (leadered) mRNAs begins with the formation of a complex containing the 30S ribosomal subunit. Although the structural elements of the mRNA, such as the SD sequence of the TIRs, when present, may contribute to the thermodynamic stability of the productive 30S–mRNA interaction, thereby favoring the selection of the correct start site of the mRNA, the initiation site is selected kinetically by the 30S ribosomal subunit with the aid of the initiator fMet-tRNA whose anticodon base pairs with the initiation codon of the mRNA to form a ternary complex, the 30S initiation complex (30S IC) comprised of the 30S ribosomal subunit, fMet-tRNA, and mRNA. Both conventional and fast kinetic analyses have contributed to the elucidation of the mechanistic aspects of the translation initiation process. The steps leading to the formation of the 30S IC are schematically represented in [Figure 2\(a\)](#), while those leading to the formation of a productive 70S initiation complex (70S IC) are illustrated in [Figure 2\(b\)](#). As seen from

[Figure 2\(a\)](#), the three initiation factors bind to the 30S ribosomal subunit (steps 1, 2, 3) which contains a full complement of initiation factors when it recruits the TIR of the mRNA and the initiator tRNA. These ligands bind to the 30S subunit in stochastic order (steps 4, 5' and 5, 4') forming first two binary complexes and then an unstable pre-ternary complex in which both mRNA and fMet-tRNA are 30S-bound without interacting with each other. A first-order isomerization of this pre-ternary complex kinetically controlled by the three initiation factors (step 6), possibly followed by locking (step 7), causes the mRNA start codon to base pair in the P-site of 30S with the anticodon of fMet-tRNA to yield a 30S IC. The specific role played by the individual initiation factors in this as well as in other steps of initiation will be described later in the article. The 70S IC is generated by the joining of the large (50S) ribosomal subunit (step 8), a process which induces a conformational change in the 30S subunit and thereby causes the ejection of IF3 (step 9) and IF1 (step 10). The intrinsic guanosine triphosphatase (GTPase) activity of IF2 is also triggered in this step to generate an IF2–GDP complex (GDP, guanosine diphosphate) and inorganic phosphate. The latter is then released from the ribosome in a step (step 11) which possibly entails also the dissociation of IF2–GDP. The dissociation of IF2 leaves fMet-tRNA in the ribosomal P-site with the acceptor end near the peptidyl transferase center of the 50S subunit. Subsequently, the binding and the adjustment of the cognate EF-Tu-GTP-aa-tRNA to the ribosomal A-site (step 12) lead to the formation of the initiation dipeptide with the P-site-bound fMet-tRNA. The formation of the initiation dipeptide is a fairly slow process compared to the rate of transpeptidation during elongation.

Figure 2 Translation initiation pathway in bacteria. Scheme depicting the steps leading to the formation of (a) the 30S initiation complex and (b) the 70S initiation complex as determined through traditional and fast kinetics analyses. Further details can be found in the text.

The structures of both 30S IC and 70S IC have been obtained from three-dimensional (3D) reconstructions of the cryo-electron microscopic images and are shown in [Figure 3](#).

Structure and Function of the Initiation Factors

Overall, the three initiation factors ensure both speed and accuracy in the initiation phase of protein synthesis. The expression of the genes encoding the initiation factors is regulated so that the relative level of these proteins with respect to each other remains constantly equimolar and their level remains constant at approximately 15% of the ribosomes. Only cold shock causes an imbalance of this ratio because while synthesis and assembly of the ribosomes slows down the genes encoding the factors, which are among the cold-shock genes, are actively expressed.

The structural properties and specific roles of the initiation factors are outlined next.

IF1

Structure

This protein, encoded by *infA*, consists of ~70 amino acids (71 in *Escherichia coli*) and its structure consists of a rigid

Figure 3 Structure of the ribosomal translation initiation complexes obtained by cryo-EM. (a) Positions of P-site bound fMet-tRNA, IF2, and IF1 in the 30S initiation complex and (b) position occupied by the acceptor end of fMet-tRNA and IF2 before and after GTP hydrolysis in the 70S initiation complex.

five-stranded β -barrel from which protrude the short, disordered, and highly flexible N- and C-terminal tails ([Figure 4 \(a\)](#)). This structural motif, known as the 'OB fold', is characteristic of a class of proteins that interact with oligosaccharides or with oligonucleotides and RNA, as is the case of IF1.

Figure 4 Three-dimensional structures of the initiation factors. (a) β -Barrel structure of *E. coli* IF1 in solution as determined by NMR spectroscopy; (b) predicted modular structure of bacterial IF2 based on the crystal structure of its archaeal homolog (eIF5b) and on the NMR solution structure of *Bacillus stearothermophilus* IF2C1 and IF2C2. The structures of the N-terminal domain and subdomain G1 are not known and these parts of the molecule are not shown. The nomenclature of the domains and subdomains is that accepted for the bacterial IF2; (c) crystallographic structure of *B. stearothermophilus* IF3 displaying the N domain (NTD), the linker, and the multifunctional C-domain (CTD).

Topographical localization and function

IF1 binds to the 30S ribosomal subunit mainly through electrostatic interactions involving the positively charged surface of the protein and the phosphate backbone of specific regions of 16S rRNA. Several lines of evidence, including crystallographic data, show that IF1 binds in the A-site of the 30S ribosomal subunit (Figure 3(a)), more precisely in the cleft between ribosomal protein S12, the 530 loop, and helix 44 of 16S ribosomal RNA (rRNA). IF1 establishes contacts with two functionally important bases (A1492 and A1493) belonging to this rRNA helix. There is also compelling evidence that IF1 binding induces several localized and long-range changes of the 30S structure, inducing an overall rotation of head, platform, and shoulder of the 30S subunit toward the A-site. It is likely that it is through the induction of these conformational changes in the small ribosomal subunit that IF1 increases the rate of 30S initiation complex formation and increases the rates of association/dissociation of ribosomal subunits, the latter activity being probably very important in favoring the ribosome dissociation activity of IF3 (Figure 5(c)).

In light of its A-site localization, it has been suggested that IF1 might block the premature access of aminoacyl-tRNA to the A-site during 30S initiation complex formation, thereby contributing to the fidelity of translation initiation. Furthermore, recent data have shown that the translation initiation fidelity function of IF3 strictly requires the presence of IF1 and that the effect of IF1 is counteracted by aminoglycoside antibiotics such as streptomycin. Finally, it is well established that IF1 and IF2 mutually influence their respective interactions with the ribosome and IF1 has been regarded as a potential modulator of IF2 recycling on and off the ribosomes. These effects are likely indirect and conformationally mediated by the ribosome since,

unlike the situation existing between the archaeal and eukaryal homologs of IF1 and IF2, a direct contact between these factors on the ribosomal surface is unlikely to occur in bacteria.

IF1 is dissociated from the ribosome after IF3, during the transition from 30S IC to 70S IC (Figure 2(b), step 10).

IF2

Structure

Bacterial IF2, encoded by *infB*, is the largest initiation factor (890 residues in *E. coli*) and consists of three major parts: (1) a variable N-terminal region; (2) a highly conserved 40 kDa G-domain consisting of three subdomains, G1, G2, and G3; and (3) the C-terminal domain (25 kDa) which consists of subdomains C1 and C2. So far no 3D structure has been directly determined for the whole bacterial IF2 molecule, and structural information concerning this factor relies on the nuclear magnetic resonance (NMR) structure of subdomains G2, C1, and C2 of *Bacillus stearothermophilus* IF2 and on the crystal structure of *Methanobacterium thermoautotrophicum* eIF5b (Figure 4(b)), the archaeal homolog of IF2. The overall shape of the archaeal factor resembles a chalice whose cup is constituted by G2, G3, and N-terminal part of C1, the stem by the C-terminal part of C1 and the foot by C2. It is likely that the structures of the archaeal and bacterial factors are similar but the functions of these two proteins have little in common. The hydrophilic, positively charged, and flexible N-domain is not present in the archaeal protein and in some bacterial IF2 molecules, and is dispensable for translation both *in vitro* and *in vivo* in *E. coli*. Its role is that of anchoring the factor to the 30S ribosomal subunit until the acceptor end of an fMet-tRNA molecule is captured by the C2 domain and recruited to the ribosome. Subdomain G2 is highly homologous to equivalent domains

Figure 5 Role and mechanism of the initiation factors in determining translation initiation fidelity. (a) Complexes recognized as correct and incorrect by IF3. The figure presents a scheme of the various types of complexes containing 30S ribosomal subunit, template, and aminoacyl-tRNAs, which are subjected to positive or negative kinetic discrimination by IF3; (b) rRNA structure around the molecular gate separating the P-site from the E-site on the 30S subunit. Since IF3 affects the 30S conformation in the h44 helix and at or near bases A790 and G1338/A1339 present on either side of the gate, it is believed to open the P/E gate, thereby favoring the dissociation of incorrectly bound aminoacyl-tRNAs by allowing it to drift from the P- to the E-site; (c) the IF1-induced conformational change of helix 44 which is believed to play a role in allowing IF3 to perform its fidelity function. Further details may be found in the text.

of other GTP/GDP-binding proteins such as elongation factors EF-Tu and EF-G. This subdomain binds GTP/GDP, contains the GTPase catalytic center, and is also responsible for most of the IF2–50S subunit interaction. G2 consists of an eight-stranded β -sheet flanked by six α -helices and a 3_{10} helix. It also contains the four conserved sequence elements characteristic of GTP-binding proteins (G1/P loop, which participates in phosphate binding, the G3 and G4 loops, forming the walls of a hydrophobic pocket where the guanine moiety of GTP or GDP

is bound and G4). The switch 2 region of this subdomain is centrally located in the cup of the chalice where it makes extensive contacts to subdomains G3 and C1 and can therefore cause conformational changes resulting in profound global rearrangements of the molecule that could reach as far as 90 Å to the C-terminal region of IF2. The G3 domain is responsible, together with C1, for the IF2–30S subunit interaction. Its β -barrel structure is very similar to that of subdomain C2. Three β -strands of this domain interact closely with G2 in the vicinity of the switch

2 region. A 17-residue-long α -helix connects G3 to subdomain C1 which is characterized by a unique α - β - α sandwich fold consisting of a four-stranded parallel β -sheet flanked on both sides by two α -helices. In the archaeal aIF5b, the last 40-Å-long α -helix (H12) of C1 extends from the cup to subdomain C2, thus forming the stem of the chalice. However, several lines of evidence indicate that such a long, continuous α -helix is not present in bacterial IF2. Subdomain C2 is responsible for the specific recognition and binding of the acceptor end of fMet-tRNA and is endowed with a structure which also consists of a β -barrel fold, similar to that of G3 and to domain II of EF-Tu and EF-G.

Topographical localization and function

IF2 is the only one of the three initiation factors displaying a specific and fairly high affinity for both 30S and 50S ribosomal subunits. Its binding to the 30S ribosomal subunit is initially mediated by an interaction between the ribosomal particle and established by the N-terminal domain of the factor. This is followed by a functional interaction, established by subdomain G3, which is stimulated by IF1; this interaction is also favored when GTP is bound to IF2, whereas it is inhibited by the metabolic alarmone ppGpp, whose concentration increases when the cells are nutritionally starved. The interaction of IF2 with the isolated 50S subunit, which involves helix 89, the sarcin-ricin domain (SRD), and the L11/Thiostrepton-binding region of 23S rRNA, and partly overlaps that of EF-G and EF-Tu, is sufficient to elicit its GTPase activity.

The localization of IF2 on both 30S subunits and 70S monomers has been elucidated by cryo-electron microscopy (Figures 3(a) and 3(b)). The topographical studies clearly demonstrate that both the position on the ribosome and the conformation of IF2 change during the subsequent steps of the translation initiation pathway.

The main function of IF2 is that of recognizing and recruiting the initiator fMet-tRNA to the P-site of the 30S ribosomal subunit, contributing to the formation of the 30S IC. Subsequently, IF2 stimulates the association of the 50S subunit with the 30S IC and ensures the correct positioning of fMet-tRNA in the ribosomal P-site of the 70S IC promoting the first transpeptidation reaction (formation of the initiation dipeptide). The function of the ribosome-dependent GTP hydrolysis by IF2 is difficult to pin down, but it appears that removal of the γ -Pi after GTP hydrolysis is necessary to allow IF2 to assume a conformation compatible with the dissociation of the IF2-fMet-tRNA interaction and ultimately favor the dissociation of IF2 from the ribosome.

The fact that either GTP (under optimal growth conditions) or ppGpp (during nutritional stress) can bind to subdomain G2 of IF2 to give rise to an active and an inactive form of the molecule, respectively, and that the substrate of IF2 is fMet-tRNA whose synthesis involves molecules involved in the one-carbon metabolism of the cell, raises the interesting possibility that IF2 might behave like a sensor of the metabolic state of the cell. Thus, in addition to and because of its roles in translation initiation, IF2 may function as a global regulator, linking translational activity to the transcriptional control of stable RNA synthesis by adjusting the translational rate of the cell as a function of the allowable growth rate.

IF3

Structure

IF3 is a medium-sized protein (180 amino acids in *E. coli*) encoded by *infC*. Its structure consists of two domains (N-terminal domain (NTD) and C-terminal domain (CTD)) of approximately equal mass connected by a long lysine-rich linker which, according to NMR data, should be at least partially unstructured and flexible (Figure 4(c)). The NTD contains a globular α/β fold consisting of a single α -helix, packed against a mixed four-stranded β -sheet. The CTD possesses a two-layered α/β sandwich fold, comprising a four-stranded β -sheet which is packed against two parallel α -helices in a $\beta\alpha\beta\alpha\beta\beta$ topology. The fold of the CTD of IF3 is similar to that found in many eukaryotic RNA-binding proteins (such as U1A) and indeed this domain interacts with the 30S subunit via a protein-RNA interaction involving primarily structural elements of this domain such as strands β -7 and β -9 that contain consensus RNP motifs and two loops (L7 and L8). The two domains of IF3 interact, independently of each other, with different sites of the 30S subunit and do not interact with one another on the ribosomal surface. Several lines of evidence demonstrate that IF3 remains bound to the 30S IC until the association of the latter with the 50S subunit promotes the dissociation of the factor. It is noteworthy in this connection that the isolated CTD of IF3 not only binds to 30S subunit but is also capable of performing all the other known functions of the intact molecule while isolated NTD has no autonomous function. However, since the affinity of the CTD of IF3 for the 30S subunits is approximately two orders of magnitude lower than that of the intact molecule and since secondary contacts established by the NTD stabilize the interaction, it has been suggested that the two-domain structure is required to modulate binding and release of IF3 to and from the 30S subunit. The conformational change of the ribosome induced by subunit association would push the platform and head of the 30S subunit away from each other, thereby widening the gap between the NTD- and the CTD-binding sites. The loss of the stabilizing interaction established by the NTD would then facilitate the dissociation of IF3 from the 30S subunit while the 30S-50S inter-subunit bridges are formed.

Topographical localization and function

Whereas there is good agreement that the CTD is localized on the platform of the 30S ribosomal subunit, the ribosomal localization of the NTD is more controversial, although it seems likely that its binding site is located somewhere near the P-site of the particle.

Binding of IF3 to the 30S ribosomal subunit interferes with subunit association, thereby shifting to the left the equilibrium $30S + 50S \rightleftharpoons 70S$. In turn, this increases the pool of free 30S amenable to initiate a new round of translation. Concerning the other functions of IF3, contrary to earlier interpretations, this factor is not required for mRNA binding to the ribosome, but promotes instead a repositioning of 30S-bound mRNA, shifting it from the stand by site to the P-decoding site of the subunit. Furthermore, IF3 increases the on-rate of pre-ternary complex isomerization, which leads to 30S initiation complex formation (Figure 2(a), step 6) and thereby stimulates overall mRNA translation. However, since IF3 also

increases the off-rate of the isomerization, it can promote initiation fidelity favoring the dissociation of both aminoacyl-tRNA and mRNA from incorrectly formed 30S complexes. In fact, IF3 promotes the dissociation of the 30S IC with different rates depending on whether the 30S complex is a canonical, a noncanonical, a leaderless, or a pseudo initiation complex and is in kinetic competition with the association of the same 30S IC with the 50S ribosomal subunit to yield a 70S IC (**Figure 2(b)**). Indeed, it has been shown that whenever the 30S IC is non-canonical or non-best-fit, both the association between the ribosomal subunits and the dissociation of IF3 are much slower. The 30S ICs recognized and accepted as correct by IF3 and those kinetically discriminated against as being incorrect or noncanonical are schematically represented in **Figure 5(a)**. As to the molecular mechanism by which non-best-fit complexes are dissociated, it is clear that this is mediated by an IF3-induced conformation change of the 30S ribosomal subunit which affects the molecular gate separating the P-site from the E-site. The opening of this gate by IF3 would cause the improperly bound aminoacyl-tRNA to drift from the P- to the E-site and dissociate (**Figure 5(b)**). The dissociation would also be favored by the conformational changes caused by IF3 and IF1 on helix44 of 16S rRNA (**Figures 5(b)** and **5(c)**).

Glossary

Eukaryotic initiation factor A protein that acts in one or more steps in the process of translation initiation.

Initiator transfer RNA (tRNA) The anticodon of initiator transfer RNA is complementary to the AUG initiation codon and its structural properties differentiate it from tRNAs that decode AUG triplets during elongation. Initiator tRNA is activated by covalent linkage to methionine to form methionyl-tRNA, which is the substrate used by ribosomes to initiate protein synthesis.

Messenger RNA (mRNA) The RNA template that is translated by ribosomes to synthesize a protein.

Its coding sequence comprises consecutive triplet codons that are decoded by base pairing with the anticodon of aminoacylated tRNAs, and that therefore determine the amino acid sequence of the resulting protein.

Ribosome The complex macromolecule that catalyzes mRNA template-directed protein synthesis. Its two subunits both consist of ribosomal RNA and proteins. The 40S subunit binds mRNA and the anticodon end of tRNA; the 60S subunit aligns the aminoacyl ends of tRNAs and catalyzes peptide bond formation.

Translation initiation, the first stage in protein synthesis, is the process of assembly of large (60S) and small (40S) ribosomal subunits to form an 80S ribosome containing initiator transfer RNA (tRNA) (Met-tRNA^{Met}) that is base paired to the initiation codon of a messenger RNA (mRNA) in the ribosomal peptidyl (P) site. This process is mediated by at least 11 eukaryotic initiation factors (eIFs) and proceeds via the sequential formation of intermediate complexes. Initiation is the rate-limiting step of translation, and is a major focus for pathways that regulate gene expression.

The Structure of Eukaryotic mRNAs

Nearly all eukaryotic mRNAs have a 5'-terminal 7-methylguanosine (m⁷G) cap and a 3'-terminal poly(A) tail that synergistically enhance the efficiency of translation initiation. Most eukaryotic mRNAs contain a single major open reading frame (ORF) that is translated into protein, and initiation usually begins at the first AUG triplet from the 5'-end of an mRNA, which follows a 5' leader that is <100 nucleotide long. An AUG triplet can be bypassed if its context deviates from the optimal sequence GCC(A/G)CCAUGG (in which the initiation codon is underlined and the nucleotides in bold have the greatest influence), if it occurs very close to the 5'-end of an mRNA, or if the 5' leader has little secondary structure. Stable structures in the 5' leader reduce initiation efficiency whereas stable structures downstream of an AUG codon can enhance initiation at it.

The Mechanism of Translation Initiation

Translation initiation on most eukaryotic mRNAs begins with binding of Met-tRNA^{Met} to a 40S subunit, followed by ribosomal attachment at the 5'-end of an mRNA, scanning to the initiation codon and joining with a 60S subunit to form an 80S ribosome. Initiation is mediated by at least 11 eIFs

(Table 1), many of which act at multiple stages in this process (Figure 1). Initiation on a few mRNAs occurs by noncanonical mechanisms, of which the most common is 5'-end independent internal ribosomal entry.

Dissociation of Ribosomes into Free 40S and 60S Subunits

Initiator tRNA and mRNA initially bind to the 40S subunit rather than to the 80S ribosome. However, association of 40S and 60S subunits to form empty 80S ribosomes is favored under ionic conditions in the cytoplasm, and a mechanism to maintain a pool of free subunits is therefore a prerequisite for initiation. eIF1A and eIF3 shift the equilibrium between ribosomes and their subunits toward dissociation. eIF3 dissociates 80S ribosomes and, with eIF1A, prevents subunit reassociation by binding directly to free 40S subunits.

Recruitment of Initiator tRNA to the 40S Ribosomal Subunit

The initiation codon is decoded by a unique initiator methionyl-tRNA. Its sequence and structural features distinguish it from the methionyl-tRNAs that decode AUG triplets during translation elongation. These features enable eIF2 to select Met-tRNA^{Met} from the cytoplasmic pool of aminoacylated and deacylated initiator and elongator tRNAs, and also exclude Met-tRNA^{Met} from translation elongation. eIF2 is a stable heterotrimeric protein consisting of α -, β -, and γ -subunits that binds guanosine triphosphate (GTP) and Met-tRNA^{Met} to form a ternary complex. Binding of the ternary complex to a 40S subunit is strongly stabilized by eIF1A and eIF3 and yields a 43S preinitiation complex. eIF2's activity in binding Met-tRNA^{Met} is regulated; its affinity for Met-tRNA^{Met} is enhanced by prior binding of GTP whereas hydrolysis of eIF2-bound GTP toward the end

Table 1 Mammalian initiation factors

<i>Factor</i>	<i>Subunits</i>	<i>Mass (kDa)^a</i>	<i>Functions</i>
eIF1		13	Promotes scanning and the fidelity of initiation codon recognition
eIF1A		17	Ribosome antiassociation; stabilizes Met-tRNA _i binding to 40S subunit; promotes scanning
eIF2	α, β, γ	36, 39, 52	Binds GTP and Met-tRNA _i to 40S subunit; GTPase
eIF2B	$\alpha, \beta, \gamma, \delta, \epsilon$	34, 39, 50, 58, 80	Guanine-nucleotide exchange factor for eIF2
eIF3	α -I	167, 105, 99, 64, 52, 38, 35, 40, 37, 29, 25, 67	Ribosome dissociation and ribosome subunit antiassociation; stabilizes binding of the eIF2/GTP/Met-tRNA _i complex to 40S subunit; required for ribosomal binding to mRNA and scanning on the 5' leader
eIF4A		44	ATP-dependent RNA helicase/RNA-dependent ATPase
eIF4B		69	mRNA-binding cofactor for eIF4A
eIF4E		25	m ⁷ G cap-binding protein
eIF4F, eIF4E, eIF4A, eIF4G		25, 44, 176	Cap-binding complex comprising eIFs 4A, 4E, and 4G
eIF4G		176	Binds and coordinates the functions of mRNA, PABP, and eIFs 3, 4A, 4E
eIF4H		25	mRNA-binding cofactor for eIF4A
eIF5		49	GTPase-activating protein specific for eIF2
eIF5A		17	May enhance first cycle of translation elongation
eIF5B		139	GTPase; ribosome subunit joining
PABP		70	Binds the 3' poly(A) tail and promotes ribosomal binding to mRNA

^aMasses (kDa) correspond to those of human proteins and, where appropriate, to the largest isoform.

of each initiation cycle yields eIF2^γ guanosine diphosphate (GDP) which dissociates from Met-tRNA_i^{Met}, leaving it in the peptidyl (P) site of the 40S subunit. Biochemical and genetic data suggest that eIF2's γ -subunit binds Met-tRNA_i^{Met} and GTP, but despite eIF2^γ having the sequence motifs and structure characteristic of a conventional GTP-binding protein, eIF2 does not have an intrinsic guanosine triphosphatase (GTPase) activity. Hydrolysis of eIF2-bound GTP is induced by eIF5, a GTPase-activating protein specific for eIF2.

Attachment of 43S Preinitiation Complexes to mRNA

Binding of initiator tRNA to form a 43S complex is an obligatory first step before a 40S subunit can bind mRNA, which for most mRNAs is a 5' end-dependent process. Attachment of 43S complexes is enhanced synergistically by the 5'-terminal cap, the 3' poly(A) tail, and the factors that associate with these structures. The m⁷G cap is bound by eIF4E, the cap-binding subunit of the heterotrimeric eIF4F, which also contains eIF4A and eIF4G subunits. eIF4A is an adenosine triphosphate (ATP)-dependent RNA helicase that cycles in and out of the eIF4F complex. eIF4G is a large polypeptide that binds mRNA and eIF4E, eIF4A, and eIF3 and the cytoplasmic poly(A)-binding protein PABP, thereby coordinating and in some instances enhancing their activities. eIF4B and the less abundant eIF4H enhance the helicase activities of eIF4A and of eIF4F; eIF4B enhances but is not essential for ribosomal attachment to mRNA. The 3' poly(A) tail's influence is dependent on PABP which binds to it, and synergism between the cap and the 3' poly(A) tail depends on the bridging interaction of eIF4G with the m⁷G cap/eIF4E and 3' poly(A)/PABP complexes.

The eIF4F complex is required on most mRNAs to unwind the cap-proximal region to prepare it for attachment of 43S complexes. Recent studies have shown that 43S complexes can bind directly to an mRNA in the absence of eIF4F if the 5'-terminal region is completely unstructured. Ribosomal attachment likely involves protein-protein interactions between

the eIF3 component of 43S complexes and both eIF4G and eIF4B as well as direct binding of eIF3, eIF4G, and the 40S subunit to the mRNA. ATP-dependent restructuring of mRNA and ribosomal attachment to the unwound region of the 5' leader are probably coordinated by interaction of the eIF4G component of the eIF4F/PABP/mRNA complex with eIF3.

Ribosomal Scanning on the 5'-Leader

Following attachment to the 5'-terminal region of an mRNA, a 43S complex scans downstream until it locates the initiation codon, which is usually the first AUG triplet from the 5'-end. Scanning consists of ribosomal movement on the 5'-leader and inspection of it to identify the initiation codon. Recent studies have shown that ribosomal complexes containing only eIF1, eIF2, and eIF3 are intrinsically capable of ATP-independent movement on a 5'-leader if it is unstructured; eIFs 1, 1A, 4A, 4B, and 4F all contribute to the processivity of scanning. eIFs 4A, 4B, and 4F, and ATP are involved in restructuring mRNA to permit scanning and are essential for scanning if the 5'-leader contains even weak-secondary structure. Many details of the mechanism of scanning remain poorly understood, including the identity of the set of factors associated with the scanning complex, the mechanism by which helicase-mediated unwinding of structured 5'-leaders is coupled to ribosomal movement, the stage at which eIF4F dissociates from the cap and from the 43S complex and the mechanism of action of eIF1 and eIF1A.

Selection of the Initiation Codon

The scanning 43S complex stops when it encounters an AUG triplet that it recognizes as an initiation codon. This is primarily determined by base pairing between it and the anticodon of initiator tRNA, but in higher eukaryotes the sequence flanking an AUG triplet also influences its selection. Genetic analyses in yeast of mutants that permit initiation at an UUG triplet have

Figure 1 Schematic model of the pathway of 80S initiation complex formation on a model capped eukaryotic mRNA. eIF1A and eIF3 promote dissociation of the 80S ribosome into 40S and 60S subunits (Step 1). eIF2 binds aminoacylated initiator tRNA (Met-tRNA^{Met}) and GTP to form a ternary complex (Step 2). Binding of the ternary complex to a 40S subunit is stabilized by eIF1, eIF1A, and eIF3 to form a 43S complex (Step 3). The eIF4F complex binds to the 5'-terminal m⁷G cap of an mRNA and with associated cofactors creates an unstructured cap-proximal site to which the 43S complex binds (Step 4). This step may be enhanced by the poly(A)-binding protein associated with the mRNA's 3' poly(A) tail (not shown). The dashed, double-headed arrow indicates interactions that promote attachment of the 43S complex to mRNA, such as those of the eIF3 component of the 43S complex with the eIF4G subunit of cap-bound eIF4F and probably with the mRNA. The 43S complex scans downstream on the 5'-leader until it reaches the initiation codon (Step 5), which is base paired to the anticodon of Met-tRNA^{Met} in the resulting 48S complex. Hydrolysis of eIF2-bound GTP is triggered by eIF5, and probably releases of eIF2-GDP (Step 6). The stages at which eIF5 joins and eIF1, eIF1A, and eIF3 are released from the 40S subunit are not known. The GTP-bound form of eIF5B mediates joining of a 60S subunit to the resulting complex (Step 7). eIF5B-GDP is released after hydrolysis of eIF5B-bound GTP, which is induced by both ribosomal subunits. The resulting 80S ribosome is then able to begin protein synthesis (Step 8). eIF2B recycles inactive eIF2-GDP to active eIF2-GTP, which can then bind Met-tRNA^{Met} again (Step 9).

indicated that eIF1, eIF2, and eIF5 all influence start site selection. Recent studies have shown that eIF1 plays the principal role in maintaining the fidelity of initiation codon selection, for example, by destabilizing complexes aberrantly arrested at non-AUG triplets or assembled on AUG triplets that have a poor context.

Displacement of eIF2 from the 48S Complex

Establishment of base pairing between the initiation codon and the anticodon of Met-tRNA_i^{Met} stimulates eIF5-induced hydrolysis of eIF2-bound GTP in ribosomal complexes. eIF2-GDP does not bind Met-tRNA_i^{Met} or the 40S subunit and is released from the 48S complex, leaving Met-tRNA_i^{Met} base paired to the initiation codon. eIF5-induced hydrolysis of eIF2-bound GTP is involved in conversion of the scanning ribosomal complex to a complex that is arrested at the initiation codon. Mutations in eIF5 or eIF2 that alter the rate of this reaction therefore influence selection of the initiation codon. eIF2 has a much higher affinity for GDP than GTP, and GDP has a slow off-rate from eIF2, so eIF2B, a guanine nucleotide exchange factor specific for eIF2 is required to regenerate active eIF2-GTP from inactive eIF2-GDP.

60S Subunit Joining to Form an 80S Ribosome

The release of eIF2-GDP from 48S complexes that is induced by eIF5 is not sufficient to permit 60S subunits to bind to the 40S subunit/*big*/Met-tRNA_i^{Met}/*big*/factor complex assembled at the initiation codon. Subunit joining also requires eIF5B, which is a homolog of the prokaryotic initiation factor 2 and, like it, has a GTPase activity that is maximally stimulated by large and small ribosomal subunits. Subunit joining leads to the release of all initiation factors from the 40S subunit and leaves Met-tRNA_i^{Met} in the ribosomal P site. The GTP-bound form of eIF5B is active in promoting subunit joining but does not dissociate from the ribosome and instead blocks the ribosomal A site. GTP hydrolysis leads to the release of eIF5B-GDP from the 80S ribosome, so that it is able to begin polypeptide synthesis. Translation initiation therefore requires hydrolysis of two GTP molecules in reactions catalyzed by eIF2/eIF5 and eIF5B, respectively. The initial round of elongation may be enhanced by eIF5A.

Regulation of Translation Initiation

The intrinsic efficiency of translation initiation on an mRNA is determined by properties such as the degree of secondary structure in the 5'-leader and the sequence context of the initiation codon. Differences in these properties account for many of the differences in the relative levels of translation of different mRNAs. Translation initiation is also regulated either selectively on a single species or on a small subset of mRNAs, or globally on all mRNAs, in order to integrate protein synthesis with physiological demands. Translation of a single species of mRNA or of a related group of mRNAs can be

repressed by binding of a protein to a specific site on the mRNA in a manner that interferes with initiation. For example, the iron regulatory protein that binds to the 5' leader of ferritin mRNA sterically prevents it from binding to the 43S complex. More commonly, translation is regulated at a more global level by alteration of the activities of initiation factors, either as a result of phosphorylation or by binding to regulatory proteins. Phosphorylation of eIF2 α causes eIF2 to bind to and inhibit eIF2B, ultimately reducing formation of the eIF2/GTP/Met-tRNA_i^{Met} complex and thus downregulating initiation globally. Initiation on most mRNAs is cap mediated and is downregulated by a reduction in the level of active eIF4F, which can occur either by proteolysis of eIF4G (e.g. during some viral infections) or by disruption of eIF4E's interaction with eIF4G by eIF4E-binding proteins that compete with eIF4G for binding to eIF4E.

Initiation of Translation by Internal Ribosomal Entry

Translation on most eukaryotic mRNAs is initiated by end-dependent ribosomal scanning, but initiation on a few viral mRNAs is end independent and is instead mediated by an internal ribosomal entry site (IRES) that promotes binding of the 40S subunit to an internal site in the mRNA without scanning from the 5'-end. IRESs are in general large and contain significant secondary structure. IRESs from a single virus family are similar, but the size and structure of IRESs from unrelated virus families differ greatly from each other. Three groups of IRESs have been characterized in detail; each mediates initiation by a different mechanism but all involve direct, noncanonical interactions of the IRES with canonical components of the translation apparatus. They all have simpler initiation factor requirements than cap-mediated initiation, and therefore escape some mechanisms that regulate that process. IRESs have been identified in several cellular mRNAs, but little is known of the mechanisms by which they promote initiation.

Glossary

TCA cycle The tricarboxylic acid cycle.

ΔG° The standard free energy of a reaction, a constant where the products and reactants are 1 M in activity or more practically concentration.

$\Delta G'$ The free energy of a reaction that is not constant but varies with the ratio of activity of concentration of

products divided by reactions and is defined by the formalism

$$\Delta G' = \Delta G^\circ + RT \ln \frac{[\text{products}]}{[\text{reactants}]}$$

The Discoverer of the Cycle

The tricarboxylic acid (TCA) cycle was first correctly formulated by Han Krebs, who was born on 25 August 1900 in Hildesheim. He was the son of a surgeon, Georg, and mother Alma, who was to die of depression when Krebs was 19. After completing gymnasium in Hildesheim in September 1918, Krebs joined the German army signal corps until the armistice of 11 November 1918. After Completing his training in internal medicine at Gottingen, Freiburg, Munich, and Berlin in December 1925, Krebs looked for ways to obtain biochemical training. The time spent in the clinics had convinced him that it was necessary to pursue medical research. Through the influence of Bruno Mendel, who served with Krebs in the Third Medical Clinic in Berlin, and who was an acquaintance of Albert Einstein, professor of Physics at the University of Berlin, who was in turn a frequent dinner guest at the home of Otto Warburg's father, Mendel heard that Warburg was looking for an assistant and recommended Krebs. This circle of influence allowed Krebs to obtain his first paid position as an assistant to Otto Warburg at the Kaiser Wilhelm Institut für Biologie at Berlin-Dahlem (see [Figure 1](#)). This stint was to change Krebs from a physician to a biochemist. Of Warburg, Krebs wrote (1981):

Otto Warburg was the most remarkable person I have ever been closely associated with. Remarkable as a scientific genius of the highest caliber, as a highly independent, penetrating thinker, as an eccentric who shaped his life with determination and without fear, according to his own ideas and ideals.

The Kaiser Wilhelm Institute was the leading scientific research facility of its time. In addition to Warburg, its faculty included Emil Fischer, Richard Willstater, Max von Laue, Fritz Haber, Otto Hahn, Lisa Meitner, and Michael Polanyi. Otto Meyerhof, a former student of Warburg, was working in the same building and elucidated the glycolytic pathway responsible for the breakdown of glucose to lactate. Students of biochemistry who passed through Kaiser Wilhelm included, among others, Fritz Lipmann and Severo Ochoa, both of whom were to play a critical role in showing the role of coenzyme A in the TCA cycle. In addition to the discipline

and rigor required for scientific research, Krebs learned from Warburg the techniques he had developed: use of tissue slices, spectrophotometry and manometry. These techniques, most notably manometry, were fundamentally important in leading Krebs to formulate the concept of a metabolic cycle, first the urea cycle and later the TCA cycle. It is important to recognize in understanding Krebs' work that the Warburg dictum "methods are everything" was dominant. There was no theoretical master plan. Only during his later work on the thermodynamics linking of cellular redox and phosphorylation states would Krebs remark in relation to that work, "This is the first time I ever thought you could predict in biology." In his early work, Krebs was a thoroughly empiricist. He could measure the rates of reaction. He added various potential participants in a metabolic pathway, and if they increased the overall rate, then he concluded they were part of the pathway. Krebs' training is of central importance to understand the cycle. As his biographer Holmes has pointed out, "Hans Krebs took 31 years to become a well-trained independent scientific investigator, and only 9 months to make one of the most significant discoveries of his generation in his chosen field."

History of the Discovery of the TCA Cycle

After leaving Warburg's lab in 1931, Krebs obtained a position as chief medical resident in the university hospital at Freiburg, and was in charge of caring for 44 patients. With his Warburg manometer and the enzyme urease, he could measure the production of urea in liver slices. In his off-time working by himself with the assistance of a medical student, Kurt Henseleit, within 1 year, he had formulated a salts solution to mimic the composition of plasma, Krebs-Henseleit saline, the basis for modern tissue culture fluids, and had worked out the ornithine cycle responsible for the hepatic synthesis of urea from ammonia. This established for the first time that cyclic, not linear, pathways could play an important role in central metabolic processes. The process of this discovery is the subject of a detailed history dissecting the inventive processes entailed.

One of the great unsolved problems was to determine the reactions whereby foodstuffs undergo combustion to produce

Figure 1 Hans Krebs at the age of 68 in his laboratory at Oxford standing next to his beloved Warburg apparatus, which he learned to use in the laboratory of Otto Warburg and which was the major instrument used in his discovery of both the urea and the citric acid cycles. The square box in the background is a power supply for a Zeiss PMQ spectrophotometer. The spectrophotometer was first devised by Otto Warburg who also first discovered pyridine nucleotide and observed their spectral shift during oxidation/reduction. This spectral change formed the basis of many of the assays Krebs undertook in his later years. With these simple instruments and a devoted staff he worked happily in this building at the Radcliffe Infirmary until he was 81, when he died in a hospital ward in the same building in 1981 after a 2-week illness.

CO₂ and water. It was known that for glucose to undergo these reactions, it must first be broken down to pyruvate in the glycolytic pathway elucidated by Otto Meyerhof. Although in retrospect, it seems logical to assume that the idea of metabolic cycles would have been foremost in Krebs' mind when he began his investigation into the oxidative combustion of foodstuffs, a careful analysis of his writing and notebooks gives no support for this idea. Rather, his formulation of the TCA cycle was the result of the empirical methods learned in Warburg's lab. From Albert Szent-Gyorgyi, he had pigeon breast muscle minces which preserved intact, the then unknown mitochondria containing the enzymes of the TCA cycle, and could oxidatively decompose glucose to CO₂. From Warburg he had a manometer with which he could measure rates of CO₂ production. Again, he added possible intermediates and observed whether the rates of reactions increased. As he put it in his autobiography:

One way of tackling the problem of the intermediate steps of the combustion process is to test which substances, apart from carbohydrate and fat, burn most readily. The logic is that if a substance is an

intermediate then it must readily undergo combustion: if it proves to be non-combustible, it cannot be an intermediate.

In two sentences was his simple plan: the same as he had used in elucidating the urea cycle. There was no grand plan. In choosing the intermediates to be added, he was guided by others working on the same general problem. Earlier Szent-Gyorgyi had shown that addition of small amounts of succinate, fumarate, malate, or oxaloacetate could catalytically increase the rate of oxidation by pigeon breast muscle minces. Szent-Gyorgyi interpreted his findings as indicating that these compounds were not intermediates in a pathway, but rather that they served as hydrogen carriers transporting the H⁺ and electrons from foodstuffs to cytochromes. By 1937, experiments by Martius and Knoop, Krebs' teacher at Freiburg, had shown in liver that citrate was converted to aconitate, then isocitrate and α -ketoglutarate, which in turn was known to be converted to succinate. It was also from Thunberg's work that malonate could inhibit the conversion of succinate to fumarate. This presented a way for Krebs to separate the reactions of Carl Martius and Franz Knoop from those of Albert Szent-Gyorgyi. Krebs then hit on the crucial question:

So I asked myself whether perhaps oxaloacetate, together with a substance derived from foodstuffs, might combine to form citrate again, after the manner of a cycle.

Krebs began his 'Results' section on the discovery of the tricarboxylic acid cycle with the experiments or data showing the catalytic effects of citrate on respiration in pigeon breast minces. His experimental results confirmed his hypothesis. In his mind this cycle could explain the complete combustion of foodstuffs to CO₂ and water.

Into the Wilderness and Back Again

After his triumph in discovering the urea cycle in 1932 and having been invited by Max Plank to discuss his findings, in the same year, on 19 June 1933, he was forced into exile from his own homeland, to which he and his father were devoted and whose army he had served, for reasons of racial identity which he had rejected. He found refuge in Hopkins Biochemistry Laboratory at Cambridge, dependent upon the kindness of strangers.

Triumph would again be followed by rejection, after Krebs' formulation of the TCA cycle. This time, however, the rejection would not be by the Nazi's who took over his homeland, but rejection would come from his scientific colleagues. A revolutionary theory always has its critics. Krebs' tricarboxylic acid cycle, published in 1937 after being rejected by *Nature*, was no exception. By 1940, Earl Evans, who had been trained in Krebs' lab at Sheffield, and Harland Wood, one of America's most distinguished biochemists then working at Iowa State, produced evidence that when C-labeled CO₂ condensed with pyruvate to form oxaloacetate it yielded α -ketoglutarate with the entire radioactivity confined to the carboxyl group adjacent to the carbonyl group. Wood suggested that this radioactive evidence was compatible with the condensation of pyruvate with oxaloacetate forming aconitate, then isocitrate

Figure 2 The original schematic of the citric acid cycle as it appeared in an article by Krebs and Johnson in 1937, after having rejected by the editor of *Nature*. Krebs attempted to define the reversible and irreversible reactions of the cycle as he knew them at the time, but which would not be accepted as correct today. The nature of the triose combining with oxaloacetate was not known until the identification of acetyl CoA by Lipmann and Ochoa in the 1950s. The essential nature of the cycle as drawn in 1937 is however, correct to this day.

and finally α -ketoglutarate at a rapid rate. If the formation of citrate from aconitate were only a slow side reaction, then this would account for the radioactive findings. For 7 years this reasoning was accepted and Krebs changed the name of his cycle from the more euphonious citric acid cycle (see [Figure 2](#)) to the more cumbersome TCA cycle, which it bears today to accommodate the generally accepted view in the biochemical community.

Krebs confined his work to practical nutritional problems for wartime Britain, which was literally starving from the depredations of Nazi submarine attacks. Then in 1948, Alexander Ogston published a short paper in *Nature* pointing out that the three-point attachment of the symmetrical citrate molecule to the citrate synthase enzyme would confer optical properties to the product of that chemically symmetrical molecule. The citric acid cycle was back in business as Krebs pointed out in his Harvey Lecture delivered on 17 March 1949. The final confirmation of the validity of Krebs' original postulate of the citric acid cycle came from Fritz Lipmann's study of the acetylation of sulfanilamides where he identified the so-called active acetate as acetyl coenzyme A. Soon thereafter, Stern, Ochoa, and Lynen showed that the intermediate through which pyruvate enters the TCA cycle was acetyl CoA which then combines with oxaloacetate to form citrate, confirming Krebs' original formulation of the cycle.

These workers also demonstrated that not only carbohydrate, but also fats and ketone bodies form acetyl CoA. This established that the Krebs citric acid cycle not only accounted for the complete conversion of carbohydrate to CO_2 and water, but also that this cycle was the terminal pathway of the degradation of all foodstuffs, including fats and amino acids (see [Figure 3](#)). It may have been with some irony that Krebs entitled his Nobel prize speech of 11 December 1953, 'the citric acid cycle' rather than the 'TCA cycle' as it was called after the radioactive data were mistakenly interpreted to indicate that aconitate, and not citrate, was the condensation product of carbohydrate degradation. Subsequently, students of biochemistry would certainly have found the original name less fearsome than the tricarboxylic acid cycle, a name that evolved from erroneous interpretation of experimental results and was perpetuated by Krebs inherent modesty.

The TCA Cycle Today

It is now accepted that the TCA cycle is not only the metabolic pathway which accounts for the complete combustion of the product of glycolysis, pyruvate, to CO_2 and H_2O that is the pathway which accounts for the complete combustion of all foodstuffs, carbohydrates, fats, and amino acids in heterotrophic organisms. Much about the control of flux through the TCA cycle remains unknown even today. One persistent question is how cyclic pathways appear to defeat the laws of thermodynamics. It is easy to understand how a linear metabolic pathway, such as glycolysis, uses the chemical energy of the reactants to proceed from A to E. It is not so clear, however, how a pathway which goes from A to A accomplishes this feat in an apparent violation of thermodynamic imperatives.

The eight enzymes catalyzing the reactions of the TCA cycle and their equilibrium constants are listed in [Table 1](#).

The overall reaction of the TCA cycle is therefore

with sum standard free energies, ΔG° at pH 7 of $-11.7 \text{ kcal mol}^{-1}$. The sum of standard free energies of the reactions of the cycle is negative. While the sum of the standard free energies of the reactions of the cycle are negative in the direction of the cycle written, there is no complete information on the actual $\Delta G'$ of the cycle *in vivo*. The actual $\Delta G'$ of a reaction is, of course, a sum of the standard free energy, ΔG° , and a term representing the actual ratio of the concentration of products over reactants.

Without knowledge of the ratio of concentrations in mitochondria of the products over the reactants of the various eight steps of the TCA cycle, no definitive statement about the reversibility of any step can be made, although most biochemical textbooks assign one or another TCA cycle as irreversible.

The synthesis of citrate from acetyl CoA and oxaloacetate, by citrate synthase, has the largest standard free energy of any reaction within the cycle and might therefore qualify for the irreversible designation. However, the distinguished

Figure 3 The TCA cycle is now recognized as the central pathway for the complete degradation of the major foodstuffs, including carbohydrate, lipid, and proteins. It also captures the reducing equivalents which are then transferred to the electron transport system of mitochondria where the energy of their redox reactions generate the mitochondrial proton gradient used to power ATP synthesis.

Table 1 The eight enzymes catalyzing the reactions of the TCA cycle and their equilibrium constants

Enzyme	EC number	Reaction	K_{eq} at pH 7.0	ΔG° at pH7 (kcal mol ⁻¹)
Citrate synthase	4.1.3.8	Acetyl CoA + oxaloacetate + H ₂ O → citrate + CoA	2.24×10^6	-9
Aconitase	4.2.1.3	Citrate ↔ isocitrate	18	-1.8
Isocitrate dehydrogenase	1.1.1.41	Isocitrate + NAD(P) ⁺ ↔ α-ketoglutarate + CO ₂ + NAD(P)H	1.17 M	-0.01
α-Ketoglutarate dehydrogenase	Enzyme complex	α-Ketoglutarate + NAD ⁺ + CoA → succinyl CoA + CO ₂ + NADH	1.17×10^3	-4.4
Succinyl CoA ligase	6.2.1.4	Succinyl CoA + GDP + Pi ↔ succinate + GTP + CoA	3.5	-0.08
Succinate dehydrogenase	1.3.5.1	Succinate + ubiquinone ↔ fumarate + ubiquinol	6.5	-1.2
Fumarase	4.2.1.2	Fumarate + H ₂ O ↔ L-malate	4.4	-0.9
Malate dehydrogenase	1.1.1.37	Malate + NAD ⁺ ↔ oxaloacetate + NADH	2.86×10^{-5}	6.5

biochemist, Paul Srere, who spent much of his career in biochemistry studying the kinetics of citrate enzymes, argued forcefully that the citrate synthase reaction achieved near equilibrium *in vivo*. Krebs himself argued that both the NAD- and

NADP-dependent mitochondrial isocitrate dehydrogenases were in near equilibrium with the free mitochondrial [NAD⁺]/[NADH] pool. A near-equilibrium reaction is hardly compatible with irreversibility. The reaction catalyzed by the

α -ketoglutarate dehydrogenase multienzyme complex could well be irreversible, but specific knowledge allowing one to come to a firm conclusion is lacking.

What is clear is that the disposal, of the reducing power produced in the reactions of the TCA cycle, mainly in the mitochondrial electron transport system critically affects the extent and possibly the direction of the reactions of the cycle. Within the last decade, it has been established that the TCA cycle exists in the earliest surviving life forms, the archaeobacteria which developed when Earth was covered in a reducing atmosphere of CO_2 and NH_3 and no O_2 . Archaeobacteria contain a TCA cycle, which was proposed to serve as a primary anaplerotic source of metabolites and amino acids, not as the primary pathway for the degradation of foodstuffs in heterotrophs. When life forms were developing, in the absence of O_2 , the direction of the TCA cycle would have been reversed.

Whether one accepts this speculation or not, it emphasizes the intimate relationship between the TCA cycle and the production of reducing power in the form of reduced pyridine nucleotide, which serves as the primary substrate for the electron transport system. When formulated in 1937, Krebs was primarily concerned with the stoichiometry of reactions accounting for the transformation of foodstuffs into CO_2 . In 1936, Otto Warburg had just discovered NADP in red cells, so the central role of these essential cofactors was not appreciated until much later when Krebs played a crucial role in defining the redox potential of the mitochondrial $[\text{NAD}^+]/[\text{NADH}]$ ratio using principles first defined Holzer, Lynen, Bucher, and Klingenberg in defining the free cytoplasmic $[\text{NAD}^+]/[\text{NADH}]$. Krebs and his colleagues then went on to show that the redox potentials of all of pyridine nucleotides were related to one another in a coherent manner. The free cytosolic NAD couple was about -0.19 V , and hence could accept reducing equivalents from glycolysis, the free mitochondrial NAD couple was a more negative -0.28 V , providing the energy necessary for mitochondrial ATP generation, while the free cytosolic NADP system was the most negative at -0.41 V , required for the completion of the reductive synthesis of fats. While it was recognized at the time that the pyridine nucleotides were related to the free $[\text{ATP}]/[\text{ADP}][\text{Pi}]$ ratio, subtleties in the effects of free $[\text{Mg}^{2+}]$ complicated this relationship and it took another 10 years to accurately determine the equilibrium constants required to quantitatively define that relationship.

In addition to accounting for the chemical decomposition of foodstuffs, it is now recognized that the TCA cycle produces reducing power in the form of three reduced pyridine nucleotides and one reduced coenzyme Q within the mitochondria. Each of these cofactors contains two electrons. Those contained in NADH feed into the mitochondrial

electron transport system at complex I, the NADH dehydrogenase multienzyme complex. The reducing equivalents contained in reduced coenzyme Q, generated in the conversion of succinate to fumarate feed into the electron transport chain at a site with a higher redox potential than that of the mitochondrial $[\text{NAD}^+]/[\text{NADH}]$ couple. Approximately four protons are ejected from mitochondria, at each site creating a $\Delta G [\text{H}^+]$ cytosol/mitochondria, which provides the energy approximately equivalent to that of the $\Delta G'$ of ATP hydrolysis in a near equilibrium reaction catalyzed by the F1 ATPase.

It was originally thought that the TCA cycle was so fundamental that any defects in the cycle would be fatal. It is now recognized that because of its central role, not only in the degradation of foodstuffs, the TCA cycle plays a central role in generating the redox potentials not only of the mitochondrial NAD couple but also of the mitochondrial Q couple. The difference in the redox potential of these two couple, in turn, sets the magnitude of the energy of the proton gradient between the mitochondrial and cytosolic phases of the cell and thus determines the energy realized when the ATP formed by the mitochondria is hydrolyzed. The amount of realizable energy formed is a function of the amount and type of the substrate being utilized by mitochondrial TCA cycle.

Glossary

Aminoacyl-tRNA synthetases The family of enzymes that catalyze attachment of an amino acid to its cognate tRNA.

Cytokine A protein that acts as a signaling molecule, typically to activate the immune system.

Genetic code The correspondence of trinucleotide codons with amino acids used in protein biosynthesis.

Ribosome The ribonucleoprotein complex that decodes messenger RNA and catalyzes peptide bond formation.

Translation Biosynthesis of polypeptides from amino acids according to a messenger RNA template.

tRNA The small structured RNA that serves as adapter between a messenger RNA trinucleotide codon and its encoded amino acid, delivering the amino acid to the growing polypeptide chain at the ribosome.

tRNA Synthetases

Protein biosynthesis at the ribosome results in the conversion of nucleic acid genetic information into the polypeptides essential for cellular function. Peptide bond formation requires numerous protein and nucleotide cofactors in addition to the ribosome itself, and is tightly regulated to ensure accurate translation. Transfer RNA (tRNA) synthetases are key players in this synthetic pathway. Each enzyme in the family attaches a specific amino acid to its corresponding tRNA, thus defining the rules of the genetic code. Organisms use up to 20 tRNA synthetases to generate aminoacyl-tRNAs, one for each of the 20 standard amino acids. While all tRNA synthetases carry out the same fundamental chemistry, they are distinguished by their structure, regulation, and often by novel functions outside their canonical role in protein biosynthesis.

Enzymatic Reaction

tRNA aminoacylation occurs as a two-step mechanism (Scheme 1), in which both steps are catalyzed at a single enzymatic active site. In the first step, the amino acid carboxylate attacks the α -phosphate of adenosine triphosphate (ATP); synthesis of an aminoacyl-adenylate (AA-AMP) occurs with release of inorganic pyrophosphate (PP_i). The second step is transfer of the activated amino acid to either the 2'-OH or 3'-OH on the terminal adenosine of the accepting tRNA. Most tRNA synthetases catalyze AA-AMP synthesis in the absence of tRNA; exceptions are arginyl-, glutaminyl-, and glutamyl-tRNA synthetases and class I lysyl-tRNA synthetase. Some tRNA synthetases have a second editing active site that hydrolyzes mis-activated aminoacyl adenylate or mis-aminoacylated tRNA.

Accuracy

The accuracy of protein synthesis has been estimated at 1 error in 10 000 codons translated. While the codon:anticodon interaction at the ribosome is by necessity specific, the major contribution to translational accuracy arises from the specificity of tRNA aminoacylation catalyzed by the tRNA synthetases.

tRNAs

Each tRNA synthetase has a set of isoaccepting tRNA molecules that are used to translate the 61 sense codons of the genetic code. tRNAs are typically 76 nucleotides long, and have conserved secondary and tertiary structure but few conserved nucleotides. All tRNAs have the sequence cytidine-cytidine-adenosine (CCA) at their single-stranded 3'-termini and several post-transcriptionally modified bases, including ribothymidine (T) and pseudouridine (ψ) in the conserved trinucleotide T ψ C. Other nucleotides are not conserved with respect to identity, but co-vary to preserve the cloverleaf secondary structure of tRNA (Figure 1). The tertiary folded structure of tRNA is an L-shaped molecule with the amino acid accepting site and trinucleotide anticodon at the two ends of the L. During protein synthesis, the tRNA anticodon forms base pairs with its complementary mRNA codon and thus delivers its attached amino acid to the growing polypeptide chain. tRNA synthetases recognize their cognate tRNAs through identity elements typically located in the acceptor stem and anticodon loop. Some identity elements are so dominant that transplantation of one or a few nucleotides is sufficient to confer aminoacylation specificity on a noncognate or near-cognate tRNA. For example, introducing the G3:U70 wobble pair of the tRNA^{Ala} acceptor stem into other tRNAs can confer alanine acceptance, while transplanting the cytidine-adenosine-uridine (CAU) anticodon of tRNA^{Met} onto tRNA^{Val} converts the latter into a substrate for methionyl-tRNA synthetase.

Amino Acids

Selectivity of the correct amino acid is limited by potential binding interactions between each amino acid and its cognate enzyme. For some amino acids, H-bonding and hydrophobic interactions can increase binding specificity. The biggest challenge for selectivity occurs for amino acids smaller than the cognate substrate. For example, valine is one methylene group smaller than isoleucine, and fits into the active site of isoleucyl-tRNA synthetase. Mis-activation of noncognate amino acids or mis-aminoacylation of tRNA is observed for many tRNA synthetases *in vitro* and can lead to error-prone translation and cellular dysfunction if not corrected by an editing mechanism.

1. $E + AA + ATP \rightleftharpoons E-AA-AMP + PP_i$
2. $E-AA-AMP + tRNA \rightleftharpoons AA-tRNA + AMP + E$

Scheme 1 Catalysis by tRNA synthetases. In step 1, each tRNA synthetase binds its cognate amino acid (AA) and a molecule of ATP and catalyzes the condensation of aminoacyl adenylate (AA-AMP), releasing inorganic pyrophosphate (PP_i). In step 2, the activated amino acid of AA-AMP is transferred to the cognate tRNA with release of adenosine monophosphate (AMP).

Figure 1 tRNA secondary and tertiary structure. On the left is the secondary cloverleaf structure of tRNA, on the right is the three-dimensional L-shaped tRNA that is functional in aminoacylation by tRNA synthetases and in protein biosynthesis at the ribosome (yeast tRNA^{Phe}, PDB 1TRAJ).

Editing

Several synthetases have evolved additional protein domains that actively hydrolyze aminoacyl adenylate or aminoacyl-tRNA to prevent translational errors and recycle substrates. These activities are termed pre-transfer and post-transfer editing, respectively (**Scheme 2**). In addition to the integrated protein domains of tRNA synthetases that catalyze these editing reactions, isolated polypeptides have been identified that carry out editing reactions in isolation from tRNA synthetases. Examples are YbaK and AlaX proteins that efficiently deacylate misacylated tRNA^{Pro} and tRNA^{Ala}, respectively.

Two Classes of Enzymes

With the determination of tRNA synthetase primary sequences and crystal structures, the organization of the enzymes into two distinct classes became apparent. The two classes are distinguished by mutually exclusive sequence and structure motifs in their active site domains that also influence catalytic differences. The amino acids Arg, Cys, Gln, Glu, Ile, Leu, Met, Trp, Tyr, and Val are attached to their cognate tRNAs by class I enzymes. Class II enzymes attach amino acids Ala, Asp, Asn, Gly, His, Lys, Phe, Pro, Thr, and Ser to their corresponding tRNAs.

Structures

Representative structures of all 20 tRNA synthetases have been determined by X-ray crystallography. Class I synthetases contain signature motifs that include the consensus sequences His-Ile-Gly-His (HIGH) and Lys-Met-Ser-Lys-Ser (KMSKS); their catalytic core is built around a Rossmann dinucleotide binding fold. Class II synthetases contain degenerate sequence motifs that assemble into an antiparallel β -sheet structure.

- $$AA'-AMP + E \rightarrow AA' + AMP + E \text{ Pre-transfer editing}$$
- $$AA'-tRNA + E \rightarrow AA' + tRNA + E \text{ Post-transfer editing}$$

Scheme 2 Editing by tRNA synthetases. Pre-transfer editing is the enzyme-catalyzed hydrolysis of mis-acylated amino acid (AA'), while post-transfer editing is hydrolysis of noncognate amino acid (AA') from cognate tRNA.

Many tRNA synthetases can also be crystallized in the presence of their cognate tRNA. Class I enzymes approach tRNA from the acceptor stem minor groove side, while class II synthetases bind the major groove side of the tRNA acceptor stem. Because of the way class I enzymes interact with their tRNAs, an unwinding of the acceptor stem is needed for the tRNA 3'-end to reach the activated amino acid in the catalytic site (**Figure 2**).

Mechanisms

The functional consequence of the differences in structural orientation is that class I synthetases attach the amino acid first to the 2'-OH of the tRNA terminal adenosine before the amino acid is transferred to the 3'-OH for ribosomal protein synthesis; class II synthetases directly attach the amino acid to the 3'-OH. The tRNA synthetase class organization is maintained across evolution with the exception of lysyl-tRNA synthetase, which exists as either a class I or class II enzyme depending on the organism.

Alternative Pathways and Enzymes

Transamidation Reactions

While we can describe the 20 canonical tRNA synthetases, enzymes to directly aminoacylate tRNAs with asparagine and glutamine are missing in many organisms, including most bacteria, archae, and eukaryotic organelles. Routes to generate Asn-tRNA^{Asn} and Gln-tRNA^{Gln} needed for protein biosynthesis are indirect, relying on aminoacylation of these tRNAs with aspartate and glutamate by nondiscriminating aspartyl- and glutamyl-tRNA synthetases, respectively. Instead of undergoing hydrolysis, however, the mismatched tRNAs are substrates for tRNA-dependent amidotransferases. The transamidation step requires ATP and an amide donor (asparagine, glutamine, or ammonia). In addition to providing correctly aminoacylated tRNA for protein biosynthesis, the transamidation pathway appears to be the sole route to asparagine biosynthesis in some organisms.

Expansion of the Genetic Code

The standard genetic code encompasses 20 amino acids encoded by 61 sense codons; however, natural expansions have been observed and synthetic incorporation of unnatural amino acids has been accomplished. The 21st amino acid, selenocysteine (**Figure 3**), is inserted at uridine-guanosine-adenosine (UGA) stop codons using an elegant set of adaptations to the ribosomal machinery. The amino acid serine is first attached to a unique selenocysteinyl tRNA (tRNA^{Sec}) by seryl-tRNA synthetase. Chemical conversion of serine to selenocysteine is accomplished by selenocysteine synthase. Over 20 selenoproteins have been

Figure 2 tRNA synthetase structures. Left, cysteinyl-tRNA synthetase, a class I tRNA synthetase (PDB 1U0B). The bound tRNA^{Cys} acceptor stem is unwound to reach into the enzyme active site. Right, threonyl-tRNA synthetase, a class II tRNA synthetase (PDB 1QF6). The N-terminal editing domain of this enzyme is located behind the tRNA acceptor stem in this view.

Figure 3 Selenocysteine. The 21st amino acid is attached to its tRNA^{Sec} in an indirect aminoacylation pathway utilizing seryl-tRNA synthetase.

Figure 4 Pyrrolysine. Found in methanogenic bacteria, pyrrolysine is the 22nd genetically encoded amino acid and is attached to its cognate tRNA by a dedicated tRNA synthetase.

identified in humans, several of which are classified as antioxidant enzymes. Selenium is an essential trace nutrient for humans because of its incorporation into proteins as selenocysteine. A 22nd amino acid, pyrrolysine (Figure 4), has been identified in methanogenic organisms, and is cotranslationally inserted at uridine-adenosine-guanosine (UAG) stop codons using a dedicated pyrrolysyl-tRNA synthetase and tRNA^{Pyl}. As the ribosome does not appear to have a proofreading activity to identify mis-aminoacylated tRNAs, peptides or proteins containing unnatural amino acids can be generated by modifying the active site of tRNA synthetases to allow these amino acids. Such unnatural amino acids can add new functionality to proteins, allowing the introduction of novel fluorophores, reactive groups, or heavy atoms.

Novel Functions

In recent years, it has become increasingly apparent that tRNA synthetases have several functions in addition to their

housekeeping role in protein biosynthesis. These additional activities tend to be specific for a given synthetase and even a particular organism. Mitochondrial leucyl-tRNA synthetase from yeast and tyrosyl-tRNA synthetase from *Neurospora crassa* facilitate group I intron splicing. *Escherichia coli* threonyl-tRNA synthetase regulates its own expression by binding its mRNA leader sequence. Human tyrosyl-tRNA synthetase is cleaved by proteolysis into two fragments that act as cytokines in regulating blood vessel formation, while a fragment of human tryptophanyl-tRNA synthetase inhibits blood vessel formation. Some noncanonical activities depend on interactions with non-synthetase proteins, such as for human lysyl-tRNA synthetase, which interacts with the human immunodeficiency virus 1 (HIV-1) gag protein to assemble active virus particles. The human bifunctional glutamyl-prolyl-tRNA synthetase binds accessory proteins to suppress the translation of mRNAs involved in the immune response.

Synthetases in Disease and Medicine

Disease Correlations

The most common confirmed involvement of tRNA synthetases in disease is a disorder termed 'anti-synthetase syndrome', in which individuals develop antibodies against one of six members of the enzyme family; symptoms include muscle inflammation, interstitial lung disease, and arthritis. It has been determined that up to one-third of patients exhibiting chronic inflammatory muscle or skin and muscle disorders have antibodies against their own tRNA synthetases. The means by which anti-synthetase syndrome develops remains unknown. Other links between tRNA synthetases and disease are increasingly being identified. Examples include defects in glycyl-, tyrosyl-, and alanyl-tRNA synthetases in peripheral neuropathies such as Charcot-Marie-Tooth syndrome and ataxia. Several tRNA synthetases are also dysregulated in cancers; for example, the activity of methionyl-tRNA synthetase is increased in human colon cancer. A specific mutation in human mitochondrial leucyl-tRNA synthetase seems linked with type 2 diabetes mellitus, although the mechanism is not yet known.

Inhibitors as Drugs

The essential cellular function of tRNA synthetases makes this family an attractive target for discovery and development of anti-infective agents; numerous academic, biotechnology, and pharmaceutical laboratories are currently investigating tRNA synthetase inhibitors. The occurrence of natural products inhibiting tRNA synthetases lends credibility to the search for novel anti-infectives. In wide use is the anti-bacterial compound mupirocin, secreted by *Pseudomonas fluorescens*, which inhibits isoleucyl-tRNA synthetase by mimicking the isoleucine adenylylate. Borrelidin, named for its discovered action against *Borrelia* species, is secreted by *Streptomyces rochei* and inhibits eukaryotic threonyl-tRNA synthetase. More recently, a benzoxaborole compound has been shown to trap tRNA^{Leu} in the leucyl-tRNA synthetase editing site, inactivating this enzyme in a novel mechanistic manner. The primary challenge in developing anti-synthetase compounds for use other than as topical agents is identifying species-specific structural or mechanistic differences in order to target the pathogen enzyme with minimal effect on host function.

Glossary

Tropomyosin A fibrous coiled-coil protein of about 40 nm in length (MW ~70 kDa). This protein forms head-to-tail filaments and binds to both troponin and actin.

Troponin isoforms Troponin isoforms from fast and slow skeletal and cardiac muscles are encoded by different genes, except that troponin C from slow skeletal and cardiac

muscles are encoded by the same gene. The cardiac isoform of troponin is widely used clinically as a biochemical marker of myocardial injury. A specific immunoassay for cardiac isoforms of troponins T and I released into blood from injured myocardium is the standard method for detecting myocardial injury, including acute myocardial infarction.

Early Studies

In 1963, a protein factor, which was extracted from minced rabbit skeletal muscle at an extremely low ionic strength condition, was found to confer Ca^{2+} sensitivity to the contractile interaction between myosin and actin. The protein factor was called 'native tropomyosin', because several properties of the factor were similar to those of tropomyosin, which had been isolated from muscular tissue about two decades earlier. However, the factor was soon revealed to be a complex of tropomyosin and a novel protein, named 'troponin'. Troponin was shown to work as a Ca^{2+} receptor for the Ca^{2+} regulation of the contractile interaction between myosin and actin in both skeletal and cardiac muscles. In the absence of Ca^{2+} , troponin, in association with tropomyosin, suppresses the contractile interaction, and, when the Ca^{2+} concentration increases to a micromolar level, this suppression is reversed through the binding of Ca^{2+} to troponin. An immunoelectron microscopic study demonstrated that troponin is distributed at regular intervals of 38 nm along the entire length of thin filaments. This periodic distribution of troponin together with other related findings led to the proposal of the thin filament model, in which two head-to-tail filaments of fibrous tropomyosin molecules run along the grooves of actin double strands and troponin attaches to the specific region of each tropomyosin. The model visualized the essential regulatory pathways over which the action of Ca^{2+} on troponin is mediated to actin molecules through tropomyosin. These studies revealed the molecular basis for the Ca^{2+} -regulatory mechanisms of muscle contraction.

Troponin Subunits

Troponin is a complex of three different subunits: troponins I, C, and T. Troponin I, together with tropomyosin, inhibits the contractile interaction between actin and myosin. Troponin C binds Ca^{2+} , and troponin T binds to tropomyosin. The Ca^{2+} regulation of the contractile interaction takes place in the presence of all three subunits of troponin and tropomyosin.

Troponin I

Troponin I inhibits the contractile interaction between myosin and actin in the presence of tropomyosin. Through this inhibitory activity of troponin I, troponin–tropomyosin suppresses the contractile interaction in the absence of Ca^{2+} . The inhibition by troponin I is extremely weak in the absence of tropomyosin. The inhibitory activity of troponin I was first shown to be largely preserved in the cyanogen bromide fragment CN4 (inhibitory peptide region; residues 96–116) of rabbit skeletal troponin I with 181 residues. Studies with synthetic peptides later demonstrated that the region of residues 105–114 (minimum inhibitory peptide), called the 'inhibitory region' in this article, is essential for the inhibitory activity, and that the region of residues 140–148 (second actin-binding region) is also necessary for full inhibition. The N-terminal region of troponin I adjacent to the inhibitory region binds to troponin C and forms a coiled-coil structure with troponin T, whereas the C-terminal region of troponin I interacts with actin–tropomyosin and binds to troponin C in the presence of Ca^{2+} . The Ca^{2+} -dependent troponin C-binding region of troponin I is located in the helical region, called the 'switch region', adjacent to the C-terminus of the inhibitory region.

Troponin I from cardiac muscle has an additional N-terminal extension of about 30 residues. Two adjacent Ser residues in the N-terminal extension are phosphorylated by protein kinase A (PKA). The N-terminal extension interacts with the N-domain of troponin C but, when phosphorylated by PKA, dissociates from troponin C, decreasing the Ca^{2+} affinity of troponin C as well as the Ca^{2+} sensitivity of contraction. The PKA-dependent phosphorylation of the N-terminal extension is involved in the acceleration of the diastolic phase induced by β -adrenergic agonists during rhythmic contraction of cardiac muscle.

Troponin C

Troponin C is a Ca^{2+} -binding subunit of troponin, which forms a complex with troponin I and troponin T. This subunit neutralizes the suppression of the contractile interaction

between myosin and actin induced by troponin I-tropomyosin, regardless of the Ca^{2+} -concentration (neutralizing action).

Troponin C has four Ca^{2+} -binding sites, termed sites I, II, III, and VI from the N-terminus, each of which consists of a Ca^{2+} -coordinating loop rich in acidic residues flanked with two α -helical segments (E-F-hand motif). X-ray crystallographic analyses have shown that troponin C forms a dumbbell-shaped structure, in which two globular domains, the N-domain and the C-domain, are linked by a central helix. Sites I and II in the N-domain specifically bind Ca^{2+} with low affinity and function as the Ca^{2+} receptor for the Ca^{2+} regulation of contraction (Ca^{2+} -specific sites), whereas sites III and IV in the C-domain bind both Ca^{2+} and Mg^{2+} with high affinity (Ca-Mg sites) and are always occupied by Ca^{2+} or Mg^{2+} under usual intracellular conditions.

In the absence of Ca^{2+} , the region patched with hydrophobic residues in the N-domain is closed within the molecule (closed conformation). The binding of Ca^{2+} to the sites in the N-domain induces the hydrophobic patch to open on the surface (open conformation) and to form a complex with the helical switch region of troponin I. In cardiac troponin C, site I is lost by residue replacement in the coordinating loop. The hydrophobic patch in the N-domain of cardiac troponin C keeps the closed conformation even in the presence of Ca^{2+} and a complex formation with the switch region is required to reach the open conformation. The C-domain of troponin C, together with troponins T and I, forms a structural core in the troponin complex.

Troponin T

Troponin T is a tropomyosin-binding subunit of troponin. This peptide is the largest of the three troponin subunits and interacts with both troponin I and troponin C. Troponin T is not directly involved in the Ca^{2+} -regulatory interactions in the troponin complex, but the presence of troponin T, in addition to troponins C and I, is required for the Ca^{2+} -regulated contractile interaction to take place. The regulatory role of troponin T is to confer the Ca^{2+} sensitivity to the neutralizing effect of troponin C.

Troponin T is split into two subfragments, called 'troponin T_1 (or TnT1)' and 'troponin T_2 (or TnT2)', by treatment with chymotrypsin. In rabbit skeletal troponin T, troponin T_1 is a N-terminal subfragment of 158 residues and binds to tropomyosin through the helical region of about 80 residues, whereas troponin T_2 , a C-terminal subfragment with 101 residues, binds to tropomyosin through its C-terminal end region and interacts with troponins I and C. The Ca^{2+} -regulatory property of troponin T is retained solely in the troponin T_2 region. Within the structural core of the ternary troponin complex, the region of 47 residues of troponin T_2 forms a coiled coil with the N-terminal region of troponin I and stably binds to the C-domain of troponin C. The troponin T_1 and T_2 regions in each molecule are axially arranged on the Z-line and the filament-top sides, respectively, along the thin filament (Figure 1).

Cardiac troponin T is about 30 residues longer than skeletal troponin T at the N-terminus. In the case of human cardiac troponin T, four isoforms are produced by the alternative

Figure 1 Molecular arrangement of troponin T in the thin filament. The T_1 and T_2 regions of troponin T are located at the near side (Z-line side) and far side (filament-top side), respectively. Reproduced from Ohtsuki I (1980) Functional organization of the troponin-tropomyosin system. In: Ebashi S, et al. (eds.) *Muscle Contraction: Its Regulatory Mechanisms*, pp. 237–250. Tokyo: Japan Scientific Society Press; Berlin Heidelberg, New York: Springer-Verlag, with permission from Japan Scientific Society Press and Springer Science+Business Media.

splicing of exons in this N-terminal extension. The Ca^{2+} -sensitivity of contraction is affected differently by these isoforms of troponin T.

Regulatory Function of Troponin

The essential process of Ca^{2+} regulation in the ternary complex of troponin consists of two complementary interactions: an inhibitory interaction of troponin I with actin-tropomyosin and a Ca^{2+} -induced interaction between troponin I and troponin C. In the absence of Ca^{2+} , the contractile interaction is suppressed by the inhibitory action of troponin I and, in the presence of Ca^{2+} , the suppression by troponin I is reversed through the Ca^{2+} -induced interaction of troponin C with troponin I.

Troponin I alone, in association with tropomyosin, suppresses the interaction between myosin and actin. The suppression by troponin I-tropomyosin is neutralized by troponin C regardless of the Ca^{2+} concentration, although a complex of troponin I-C binds to actin-tropomyosin in the absence of Ca^{2+} but not in the presence of Ca^{2+} . The presence of troponin T, in addition to troponins C and I, is required for the suppression of the contractile interaction through the inhibitory action of troponin I within the ternary troponin complex, in the absence of Ca^{2+} . According to the X-ray crystallographic

analysis of the core domain of troponin, the N-terminal region of troponin I and the C-terminal region of troponin T (troponin T₂) form a stable coiled-coil structure, whose C-terminal ends are adjacent to both the inhibitory region of troponin I and the C-terminus of troponin T₂ that binds to tropomyosin. This close apposition of the inhibitory region of troponin I and the C-terminus of troponin T₂ suggests that the inhibitory activity of troponin I in the absence of Ca²⁺ is protected by both the stable coiled-coil formation with troponin T₂ and the binding of troponin T₂ to tropomyosin, against the neutralizing action of troponin C. Troponin T₁, by binding of its helical region to tropomyosin, would contribute to the overall arrangement of the core domain along the thin filament. There is also evidence indicating that tropomyosin enhances the affinity for troponin I of one of the seven actins in the 38-nm period, which is located at the specific region of each tropomyosin. The inhibitory effect of troponin I on the actin, which probably has a high affinity for troponin I, is mediated to the other actin molecules via tropomyosin.

In the presence of Ca²⁺, the hydrophobic patch region in the regulatory N-domain of troponin C becomes open on the surface of the molecule. The Ca²⁺-bound N-domain with the open conformation then binds to the switch region of troponin I and induces the inhibitory region of troponin I, which is adjacent to the N-terminus of switch region, to dissociate from actin and consequently to trigger the contractile interaction of actin with myosin.

To explore the physiological properties of troponin, it is critically important to remove and replace each subunit of troponin in myofibrils or skinned fibers and to compare the mode of Ca²⁺ regulation with that of the original one. Examinations along this line have been partly realized by treating skinned muscle fibers or myofibrils with excess amounts of troponin T. The added troponin T expels the intrinsic ternary troponin complex by binding to tropomyosin. Through overall depletion of troponins C and I after treatment with troponin T, the force of skinned fibers is activated at a level slightly lower than the maximum force of intact fibers regardless of the Ca²⁺ concentration, and is suppressed by the reconstitution with troponin I. The original Ca²⁺-sensitive force generation is fully restored by the subsequent reconstitution with troponin C. These findings indicate that the force generation of skinned fibers is suppressed by the inhibitory activity of troponin I and de-suppressed through the binding of Ca²⁺ to troponin C. These findings are also consistent with the findings that troponin elevates the maximum level of Ca²⁺-activated tropomyosin-actomyosin adenosine triphosphatase (ATPase) activity. This activating effect of troponin is a minor mechanism in vertebrate striated muscle, but it is a principal mechanism of troponin from scallop muscle. The particular property of scallop troponin is to bind Ca²⁺ solely by the site IV in the C-domain of troponin C, which is not the regulatory site but the structural site in vertebrate troponin C. The activating action of human cardiac troponin is also known to be enhanced by two missense mutations of troponin T causing hypertrophic cardiomyopathy (HCM), which are located in the structural core of the troponin complex.

The above considerations also indicate that all three subunits of troponin within skinned or permeabilized muscle fibers can be selectively replaced by the added troponin

subunits, through treatment with excess troponin T or troponin CIT complex. The exchangeability of the binding of troponin T to tropomyosin in the thin filament has been used to incorporate various isoforms or recombinant mutants of troponin into skinned fibers. Through this procedure, troponin was shown to be involved in the length-dependent activation mechanisms of force development in cardiac muscle. Extensive functional analyses have been made of the large number of human cardiac troponin mutations associated with inherited cardiomyopathies.

Troponin and Genetic Disorders

Genetic analysis has shown that inherited cardiomyopathies are associated with the mutations in genes for sarcomeric and cytoskeletal proteins, including cardiac troponin. Nearly one hundred mutations in the genes for cardiac troponin isoforms have been reported to cause familial cardiomyopathies. HCM is characterized by an asymmetric left ventricular hypertrophy and impaired diastolic function. Dilated cardiomyopathy (DCM) is characterized by ventricular dilation and systolic dysfunction. Restrictive cardiomyopathy (RCM) is the least common of the inherited cardiomyopathies and is characterized by impaired diastolic filling of the left ventricle, normal or near-normal systolic function, and normal ventricular wall thickness. These disorders are associated with a high incidence of heart failure and sudden death.

Troponin T Mutations

The cardiac troponin T mutations causing HCM were the first troponin mutations identified in inherited cardiomyopathies. Functional analyses of the mutations were performed with the troponin-exchange technique in skinned cardiac muscle. In 1998, missense mutations of troponin T (Ile79Asn, Arg92Gln) were found to increase the Ca²⁺ sensitivity of isometric force but not to affect the maximum level and cooperativity. Fifteen troponin T mutations causing HCM were subsequently reported to have the Ca²⁺-sensitizing effects on the skinned fiber force generation and myofibrillar or actomyosin ATPase activity. By contrast, a deletion mutation of troponin T (Δ Lys210)-causing DCM was found to decrease the Ca²⁺ sensitivity of contraction without causing any significant changes in the maximum level or cooperativity, and other mutations of troponin T-causing DCM have also been reported to decrease the Ca²⁺ sensitivity of force generation and ATPase activity of myofibrils or actomyosin (Figure 2).

These functional studies of the troponin T mutations emphasize the importance of the changes in the Ca²⁺ sensitivity as the critical functional consequences in determining the phenotypes of HCM and DCM associated with troponin mutations. In cardiac muscle, the Ca²⁺-activated force achieved during twitch contraction is usually less than half the maximum, and consequently alterations of the Ca²⁺ sensitivity greatly influence the force generation in both the systolic and diastolic phases. The increased Ca²⁺ sensitivity enhances systolic contraction and delays diastolic relaxation, whereas the decreased Ca²⁺ sensitivity reduces systolic contraction. These changes are consistent with the distinct phenotypes in HCM or

Figure 2 Distribution of mutations of troponins T and I causing HCM, DCM, and RCM in human cardiac troponin. The diagrammatic illustration of Ca^{2+} -bound cardiac troponin in the figure is based on the X-ray crystallographic structure of the core domain of the human cardiac troponin CIT₂-complex. Troponin subunits are indicated by different colors: green (troponin I, TnI), sky blue (troponin T, TnT), and pink (troponin C, TnC). The core domain is composed of two subdomains: an IT arm and a regulatory head (indicated by solid lines). The IT arm is the structural core of troponin which is composed of the C-domain of troponin C, troponin I (H1(I), H2(I)), and troponin T₂ (H1(T₂), H2(T₂)), whereas the regulatory head is a complex of the N-domain of troponin C and the H3(I) switch helix of troponin I. The inhibitory region (IR), which is not visualized in the crystal structure, is indicated by a thick broken line between the two helical regions, H2(I) and H3(I). Other regions of troponin subunits outside the core domain are indicated by thin broken lines. The positions of mutations of troponins T and I, of which the Ca^{2+} -sensitizing and -desensitizing actions have been demonstrated on the skinned fiber force and myofibrillar or actomyosin ATPase activity, are indicated by different colors; red (HCM), dark blue (DCM), and purple (RCM). The mutations, whose effects were examined solely on actomyosin or acto-S1 ATPase, are indicated by *italic letters*. Adapted from Ohtsuki I and Morimoto S (2008) Troponin: Regulatory function and disorders. *Biochemical and Biophysical Research Communications* 369: 62–73, with permission from Elsevier.

DCM: HCM is characterized by impaired diastolic function accompanied by ventricular hypertrophy, whereas DCM is characterized by reduced systolic function and ventricular wall dilation. The essential importance of the decreased Ca^{2+} sensitivity for the pathogenesis of DCM was demonstrated in the knock-in mouse model of DCM caused by the Lys210-deletion mutation of troponin T.

Troponin I Mutations

Mutations of cardiac troponin I causing HCM, DCM, and RCM have been reported. The Ca^{2+} -sensitizing and Ca^{2+} -desensitizing effects, which had been shown by mutations of troponin T causing HCM and DCM, respectively, are also demonstrated by the mutations of troponin I. Analysis of seven examined mutations causing HCM has shown the Ca^{2+} -sensitizing effects on the skinned fiber contraction and myofibrillar or actomyosin ATPase activity. Two missense mutations causing DCM have been reported to decrease the Ca^{2+} sensitivity of actomyosin ATPase activity (Figure 2).

RCM is an uncommon disorder, and six mutations of troponin I associated with RCM (Leu144Gln, Arg145Trp, Ala171Thr, Lys178Glu, Asp190Gly, and Arg192His) were reported.

Although RCM is characterized by restrictive filling and little or no ventricular hypertrophy, these mutations increase the Ca^{2+} sensitivity of skinned fiber contraction and myofibrillar or actomyosin ATPase activity, as do mutations causing HCM. The extent of Ca^{2+} sensitization due to mutations causing RCM is, however, greater than that due to mutations causing HCM. The Ca^{2+} -sensitizing effects due to most mutations causing RCM are accompanied by both elevated minimum force levels and the decreased maximum force generation, whereas the Ca^{2+} -sensitizing effects of mutations causing HCM are accompanied only by elevated resting forces. Most mutations causing RCM and HCM are located in the inhibitory region and its C-terminal side sequence (Figure 2). These findings suggest that common mechanisms exist for the pathogenesis of RCM and HCM. Consistent with this view, a mutation (Asp190Gly) was found to be associated with the mixed appearance of RCM and HCM in a large family. Two mutations

(Lys178Glu and Arg192His) were *de novo*, and two mutations (Leu144Gln and Ala171Thr) were identified only in the probands. Three mutations (Leu144Gln, Arg145Trp, and Asp190Gly) were later identified in patients who had HCM with a restrictive phenotype.

Troponin C Mutations

The Ca^{2+} -sensitizing effects on skinned fiber force generation and actomyosin ATPase activity have been documented by four mutations of troponin C causing HCM, which are distributed in both the N- and C-domains. A mutation causing DCM, located at the C-terminus, was reported to have no significant Ca^{2+} -desensitizing effect on the skinned fiber force generation but was shown to decrease the Ca^{2+} sensitivity of acto-S1 ATPase activity.

Knock-In Mouse Model of DCM Caused by Troponin T Mutation

Knock-in mice, in which three base pairs coding for the amino acid residue Lys210 in cardiac troponin T were deleted from the endogenous cardiac troponin T gene, have demonstrated the critical role of myofilament Ca^{2+} sensitivity in the pathogenesis of DCM. Skinned cardiac muscle fibers from these mutant mice showed a significant decrease in the Ca^{2+} sensitivity of force generation. However, intact cardiac muscle fibers from mutant mice did not show any significant decrease in force-generating capability, which was expected to be caused by the decreased Ca^{2+} sensitivity of myofilaments. Analysis with fura-2, a Ca^{2+} -indicator, revealed a significant increase in the peak amplitude of the Ca^{2+} transient in cardiomyocytes of mutant mice and significant increases in the phosphorylation of ryanodine receptor-2 and of phospholamban catalyzed by a cyclic adenosine monophosphate (cAMP)-dependent protein kinase. These findings suggest that the Ca^{2+} transient is augmented through increased cAMP levels to compensate for the decreased myofilament Ca^{2+} sensitivity and to maintain the force-generating capability of cardiomyocytes. Nevertheless, the mutant mice had markedly enlarged hearts and extremely high rates of premature sudden death due to fatal arrhythmia, closely mimicking the phenotypes of human DCM. These outcomes indicate that the decreased myofilament Ca^{2+} sensitivity leads to global remodeling of the heart to compensate for an inevitable decrease in cardiac function with sacrifice of the electrophysiological stability. As expected, oral administration of a Ca^{2+} sensitizer, known to increase the myofilament Ca^{2+} sensitivity in cardiac muscle, was found to markedly reduce the heart size of mutant mice and almost completely prevent the sudden death.

Troponin Mutations and Regulatory Function

Within Ca^{2+} -bound human cardiac troponin, the core domain consists of two subdomains, an IT-arm and a regulatory head (Figure 2). In the regulatory head, the Ca^{2+} -bound N-domain of troponin C forms a complex with the short helical switch region, H3(I), of troponin I. The inhibitory region of troponin I, which is adjacent to the switch helix region, is located near the core domain and is separated from actin, in the presence of

Ca^{2+} . In the IT-arm region, the C-domain of troponin C binds to both troponin I helix, H1(I), and the troponin T₂ helix, H2(T₂), and, the coiled-coil backbone is formed by troponin T₂ helix, H2(T₂), and troponin I helix, H2(I). The IT-arm region is connected to tropomyosin through the two regions of troponin T: the helical region of troponin T₁ and the C-terminal end region of troponin T₂.

Most mutations of troponin T and troponin I are outside the core domain. Their locations strongly indicate that these mutations affect the Ca^{2+} sensitivity of contraction mainly through interactions with tropomyosin and actin, rather than through conformational or interaction changes within the core domain. This view is consistent with the fact that only a small number of mutations causing HCM or DCM have been reported in the genes for the cardiac troponin C molecule, which is located within the core domain. Troponin T mutations are distributed in both the troponin T₁ and troponin T₂ regions, where mutations causing HCM would induce Ca^{2+} -sensitizing effects by impairing the interactions with tropomyosin and where mutations causing DCM would decrease Ca^{2+} sensitivity by modulating the interactions with tropomyosin and actin. Most troponin I mutations are located in the inhibitory region or the C-terminal regulatory region. Mutations of troponin I causing either HCM or RCM would impair the inhibitory interaction with actin–tropomyosin or modulate the neutralizing interaction with troponin C or both, thereby increasing the Ca^{2+} sensitivity of contraction, which is accompanied by the changes in minimum or maximum force levels or both.

Tubulin and Its Isoforms

Glossary

Dynamic instability Nonequilibrium behavior of microtubules by which they can stochastically switch between phases of growth and shrinkage. It originates from the hydrolysis of guanosine triphosphate (GTP) in β -tubulin and can be regulated by the interaction of tubulin/microtubules with cellular factors and antimetabolic agents.

Microtubules Cytoskeletal polymers made of $\alpha\beta$ -tubulin essential for cell transport and cell division. They are polar,

dynamic, and are regulated through the cell cycle by their interaction with stabilizers and depolymerizers.

$\alpha\beta$ -Tubulin dimer Essential, highly conserved protein dimer present in all eukaryotes that self-assembles forming microtubules. It is the target of antimetabolic drugs with anticancer potential.

γ -Tubulin Tubulin isoform most abundant at microtubule-organizing centers where it is involved in microtubule nucleation. It forms higher-order complexes with associated proteins.

Tubulin is an $\alpha\beta$ dimeric protein that self-assembles into microtubules and is present in all eukaryotes. Tubulin is highly conserved across species, reflecting the sequence constraints imposed by microtubule structure and function. Both α - and β -subunits exist in numerous isotypic forms and undergo a variety of posttranslational modifications. Tubulin assembly and disassembly, which are linked to guanosine triphosphate (GTP) hydrolysis, make the microtubule network dynamic in both time and space to accommodate the needs of the cell during the cell cycle. Purified tubulin retains its self-assembling capabilities, allowing the biochemical and biophysical characterization of the microtubule polymerization and depolymerization processes. A variety of proteins interact with tubulin in the cell, affecting the stability of microtubules and their function. Numerous ligands bind to tubulin and influence its assembly properties, which include several drugs that have proved to have anticancer properties.

γ -Tubulin is a rarer tubulin isoform involved in the nucleation of microtubules at microtubule-organizing centers (MTOCs). Recently, additional tubulin isoforms of yet ill-defined function have been identified.

$\alpha\beta$ -Tubulin

Physical Properties

General

Tubulin α - and β -subunits have molecular weights of ~ 50 kDa and are 36–42% identical and 63% homologous. Both tubulin subunits bind guanine nucleotides. The binding to α -tubulin at the N-site is nonexchangeable, while the binding to β -tubulin at the E-site is exchangeable. Magnesium increases the affinity of the β -subunit for GTP with respect to guanosine diphosphate (GDP). Nucleotide in oligomeric tubulin or in microtubules does not exchange with the solution, except for terminal subunits at microtubule ends.

Neuronal cells are particularly rich sources of tubulin because microtubules are required for axonal transport. Neural tissue contains sufficient tubulin to allow tubulin purification by repeated cycles of 37°-induced assembly and 0°-induced

disassembly, with intervening centrifugation to alternately pellet microtubules or impurities. The yield of tubulin from 1 kg of brain and yeast is ~ 150 and ~ 5 mg, respectively. The assembly of purified tubulin can be assayed by light scattering, X-ray scattering, centrifugation, and electron microscopy.

Isotypes and posttranslational modifications

Tubulin exists in different isotypic forms, the biological significance of which is still a matter of debate. The number of tubulin isotypes increases with the organism complexity. Although yeast has only two α - and one β -tubulin isotypes, higher eukaryotes have up to eight β - and six α -tubulin isotypes. Certain isotypes have been found to be tissue specific, and differential expression of β -tubulin isotypes has been observed during the cell cycle. Some of these isotypes have been shown *in vitro* to have different relative stabilities, and such differences seem important for the response of the cell to antitubulin, anticancer drugs. The majority of differences between isotypes localizes within the last 15 residues of the sequences, a region that has been identified as important in the interaction of microtubules with microtubule-associated proteins (MAPs), pointing to a possible relevance for the functionality of microtubules in the cell.

Both tubulin subunits can be extensively altered by posttranslational modification, including dephosphorylation/tyrosination, acetylation/deacetylation, phosphorylation, polyglutamylation, and polyglycylation. All of these modifications, except for the acetylation of α -tubulin at Lys 40, occur at the divergent, highly charged C-terminal end of α - and β -tubulin. As for the different tubulin isotypes, the functionality of the posttranslational modifications is still a matter of debate. Certain modifications were initially identified as causing microtubule stability, and had been later postulated as the effect, not the cause of microtubule stability.

Structure

The structure of tubulin was initially solved by electron crystallography of zinc-induced two-dimensional tubulin sheets stabilized with the anticancer drug taxol. α - and β -tubulin have basically the same secondary structure, each being made of a

core of two β -sheets surrounded by helices as shown in **Figure 1**. The N-terminal domain forms a Rossmann fold with the nucleotide-binding site at the C-terminal end of six parallel strands that are surrounded by five helices. An intermediate domain containing the binding site of taxol and colchicine is formed by a mixed β -sheet of four strands and five surrounding helices. The C-terminal domain contains two long helices that overlap the previous two domains and constitute the outside crest of the protofilaments in the microtubule to which motor molecules bind. The nucleotide sits at the interface between subunits along the protofilament. The N-site in α -tubulin is buried within the dimer, while the E-site in β -tubulin is partially exposed in the dimer but occluded in microtubules.

The X-ray crystallographic structure of tubulin in a nonassembled state has been obtained while bound to a fragment of the depolymerizer protein RB3 and bound to a variety of depolymerizing drugs (e.g., colchicine and vinca alkaloids). Comparison of the straight tubulin dimer in the assembled sheets used for electron crystallography and these curved, depolymerized tubulin shows a conformational change in each monomer subunit that correspond to a hinge motion between the N-terminal and intermediate domains, as well as a displacement of the H7 helix. Lower-resolution structures have been proposed for structural mimics of the intermediates in the process of assembly (sheets) and disassembly (peels). How much differences in curvature in tubulin reflect nucleotide state (GTP vs. GDP), assembly state (assembled vs. disassemble), or a mixture, are still a matter of debate.

Figure 1 Ribbon diagram for the structure of $\alpha\beta$ -tubulin corresponding to a view from the inside of the microtubule with the plus end at the top. β -Tubulin (top) is bound to GDP, while α -tubulin (bottom) is bound to GTP. The color scheme highlights the three domains in the structure of each monomer: green for N-terminal, nucleotide-binding domain (helix H7 or core helix is shown in lime), second or intermediate domain in blue, and C-terminal domain in purple.

Tubulin homologs have now been found in eubacteria and archaeobacteria, including the ubiquitous FtsZ, essential for cytokinesis, and plasmid-encoded proteins involved in plasmid segregation (e.g., TubZ).

Synthesis and folding

Tubulin synthesis in cells is regulated by a process in which an increased subunit concentration leads to specific degradation of β -tubulin messenger RNA. In animal cells, there is a mechanism to assure equivalent synthesis of α - and β -subunits. For its correct folding tubulin requires the cytosolic chaperonin CCT (chaperonin containing TCP1; also referred to as TriC, TCP1, or Ct-cpn60), a hetero-oligomer formed by eight different subunits assembled into a hexadecamer of two double rings. Folding by CCT requires cycles of binding and full release, each cycle consuming one adenosine triphosphate by the chaperonin. In addition, tubulin requires additional chaperonin cofactors that bind sequentially to α - and β -monomers and are necessary for the formation of the tubulin heterodimer. Folding cofactors are also important in regulating α/β -tubulin ratios.

Tubulin Polymerization

Microtubule assembly and structure

The tubulin sequence and structure contain the information required for its self-assembly into polar, dynamic microtubules, which, in turn, interact with a variety of cellular factors. Tubulin dimers bind head to tail, making linear protofilaments, which associate in a parallel fashion giving rise to a polar microtubule. In a cell, the so-called minus end of a microtubule, capped by α -subunits, is attached to the centrosome where γ -tubulin and related proteins nucleate microtubules. The more dynamic plus end, capped by β -subunits, binds the kinetochore in mitosis.

The orientation of the tubulin subunits in the microtubule is such that the C-terminal helices form the crest of the protofilaments on the outside surface, making them an essential part of the binding site for motor proteins (kinesins and dyneins) and MAPs. The taxol-binding site is on the inside surface of the microtubule, and close to lateral interactions. The lateral contact between protofilaments is dominated by the interaction of the so-called M-loop in the second domain with loop H1-S2 and helix H3 in the N-terminal, nucleotide-binding domain.

The plus end of the microtubule is crowned by β -tubulin subunits exposing their nucleotide end to the solution, while the minus end is crowned by α -subunits exposing their catalytic end. When a dimer is added to a plus end, its catalytic end contacts the E-site nucleotide of the previous subunit forming the interface that should bring about hydrolysis.

Dynamic instability and GTP cap model

Microtubules are highly dynamic and can switch stochastically between growing and shrinking phases, both *in vivo* and *in vitro*. This nonequilibrium behavior, known as dynamic instability, is based on the binding and hydrolysis of GTP by tubulin subunits. Only dimers with GTP in their E-site can polymerize, but following polymerization this nucleotide is hydrolyzed by interactions with the previous tubulin dimer and then becomes nonexchangeable. In the GTP cap model,

the unstable body of the microtubule made of GDP-tubulin is stabilized by a layer of tubulin subunits at the ends that still retain their GTP. When this cap is stochastically lost, the microtubule rapidly depolymerizes. Depolymerization may occur by weakening of lateral contacts at the ends, and the consequent release of the constrained GDP subunits into a curved, lower energy, conformational state.

Microtubule assembly and stability are further modified in the cell by interaction with cellular factors that stabilize or destabilize microtubules at different points in the cell or at different stages in the cell cycle. Measurement of microtubule dynamics *in vitro* and *in vivo* by differential interference contrast (DIC) or fluorescence microscopy yields the rate constants for addition of tubulin-GTP and loss of tubulin-GDP subunits at the two microtubule ends, as well as the rates of catastrophe (switch from growth to shrinkage) and rescue (switch from shrinkage to growth). A variety of drugs bind to tubulin and affect its polymerization. Microtubule-depolymerizing drugs, such as colchicine, nocodazole, vinca alkaloids, or podophyllotoxin, have a much higher affinity for the dimer than for tubulin in microtubules, so that disassembly is caused by their mass action effect. At substoichiometric concentrations, tubulin-drug subunits bind to the microtubule ends and form caps that dramatically modify microtubule dynamics. Microtubule-stabilizing drugs such as taxoids, epothilones, or discodermolide act by binding preferentially to the polymerized form of tubulin.

An alternative microtubule behavior is treadmilling, a net flow of subunits from the plus to the minus end without a significant change in microtubule length.

Antimitotic tubulin ligands

Recent years have seen the discovery of numerous tubulin ligands with antimitotic properties and anticancer potential. Concerning their binding site these agents can be classified into three main groups: those that bind tubulin at the colchicine-binding site; those that bind it at the vinblastine site; and those that bind it at the taxol site. Functionally, these antimitotic ligands can be separated into two classes: those that inhibit microtubule assembly (e.g., the colchicine and vinblastine families) and those that promote microtubule assembly and stabilization (e.g., the taxol family). In spite of these differences, the main action of all these agents seems to be to cause mitotic arrest by inhibiting normal dynamic instability at very low concentrations.

The colchicine-binding site is located at the monomer-monomer interface within the dimer, in agreement with a model of colchicine action in which binding and stabilizing a bent conformation of the dimer inhibits its polymerization. Vinblastine-like compounds bind at the longitudinal interface between dimers, also stabilizing a bent protofilament structure. Taxol binds to β -tubulin, near the M-loop and the site of lateral interactions, in a hydrophobic pocket that in α -tubulin is occupied by eight extra residues (see Figure 2). New microtubule-stabilizing agents with promise for cancer treatment, such as epothilones, discodermolide, eleutherobin, and the sarcodictins, while very different in structure, all seem to compete with taxol for the binding to a common site. It has been proposed that taxol stabilizes lateral contacts, or alternatively, that it acts as a bridge that holds the N-terminal and

Figure 2 Anticancer drug taxol at its tubulin-binding site. Tubulin is shown on a surface representation with the same color scheme as in Figure 1. Both the N-terminal and intermediate domain are part of the taxol-binding pocket.

second domains in a relative orientation that favors longitudinal contacts between subunits.

γ -Tubulin and microtubule nucleation

Crucial to their dynamic behavior and function is the nucleation of microtubules in the cell at MTOCs, to which they are attached by their minus ends. An essential role in microtubule nucleation is played by γ -tubulin, a protein with high homology to α/β -tubulins that localizes at MTOCs. γ -Tubulin forms ring structures that serve as templates for microtubule growth. The direct involvement of γ -tubulin in microtubule nucleation has been demonstrated *in vitro* using purified γ -tubulin-containing ring complex (γ TuRC) containing at least seven different proteins. There are two main models in the literature. A model based on the shape and size of the γ -TuRC is that the ring forms the first helical turn of the growing microtubule, serving as a template for longitudinal interaction with the tubulin $\alpha\beta$ dimers. An alternative model, based on the similarity of rings structures formed by $\alpha\beta$ -tubulin, γ -tubulin, and FtsZ, is that γ -tubulin forms a protofilament-like structure by longitudinal self-association that then serves as a template for lateral interaction with $\alpha\beta$ -tubulin protofilaments. The X-ray crystallography structure of γ -tubulin shows lateral contacts between proteins similar to those in microtubules, lending support to the ring model.

Rarer tubulin isoforms: δ -, ϵ -, ζ -, and η -tubulins

Four new tubulin isoforms have recently been discovered. The δ -tubulin was identified in *Chlamydomonas* mutants having abnormal basal bodies (these are microtubule structures at the base of cilia and flagella structurally similar to the centrioles in the centrosome at MTOCs). Human δ -tubulin was subsequently found in the human genome database, and shown to localize to the centrosome, where it partially colocalizes with γ -tubulin.

The ϵ -tubulin was identified from the human genome database on the basis of sequence similarity to other tubulins. Like δ -tubulin, ϵ -tubulin localizes to the centrosome, but in a cell-cycle-dependent manner: in cells with duplicated centrosomes ϵ -tubulin localizes only with the old centrosome.

Even rarer, ζ -tubulin has so far only been found on kinetoplastid protozoa where it localizes to the basal body, while η -tubulin has been found in paramecium where it may interact with γ TuRC.

Tubulins and the cell

The involvement of the microtubule cytoskeleton in a large number of essential and diverse functions requires both reliability and flexibility from the system at the expense of biochemical and structural complexity. Dynamic instability is an inherent property of microtubules, built into the $\alpha\beta$ -tubulin structure. The spatial and temporal organization of the microtubule network in the cell is obtained through the regulation of dynamic instability by an increasing number of factors that fine-tune the behavior of the microtubule system to accommodate the requirements of the cell. Regulation may happen at many different stages, via transcription of different tubulin isotypes, the control of tubulin monomer folding, the formation of functional dimers, the posttranslational modification of tubulin subunits, the nucleation of microtubules, or the interaction of microtubules with numerous associated factors, especially those that bind to and affect the behavior of microtubule ends. Tubulin-binding drugs can dramatically disrupt the finely tuned behavior of microtubules. Finally, while γ -tubulin is known to be essential for microtubule nucleation, additional tubulin isoforms, only recently discovered, have yet ill-defined functions.

Glossary

Apoptosis An orderly process of programmed cell death whereby cellular machinery undergoes changes leading to death.

Autoimmunity An immune response against self-antigens.

Cytokine Proteins made by cells that bind specific receptors that affect the behavior of other cells.

Signal transduction Term used to describe the processes inside cells used to respond to changes in their environment.

Transcription factor A protein that binds DNA to control the transcription of genes involved in a large number of normal cellular and organismal processes.

Features of Tumor Necrosis Factor Receptors

Structure

Tumor necrosis factor receptors (TNFRs) are identified by a highly conserved, cysteine-rich domain (CRD) in the extracellular portion of the protein that binds its specific ligand(s) (Figure 1). The CRD may contain six cysteines that form three disulfide bonds typically recognized by the signature sequence motif CxxCxxC. There are more than 29 members of the cellular TNFR family in mammals, and several variants of TNFRs encoded by herpesviruses and poxviruses. The cellular receptors are primarily type I transmembrane proteins (extracellular N terminus). The cytoplasmic sequence motifs and signaling properties further define the TNFR family into three subsets. The first group includes receptors that contain a death domain (DD), such as TNFR1, Fas, TRAILR1 and 2, and DR3. The DD signaling motif is important for activation of the proteolytic enzymes caspases family that regulates apoptotic cell death. A second subset includes TNFR2, LT β R, HVEM, CD27, 4-1BB, OX40, AITR, and CD30. Their cytoplasmic tails contain binding sites for the TNFR-associated factors (TRAFs) that are important for downstream nuclear factor kappa B (NF- κ B) and activator protein 1 (AP-1) activation. The third group is secreted receptors, which lack transmembrane and cytoplasmic domains, and includes DcR3 and OPG. The soluble receptors are thought to serve as decoys competing with signaling receptors for their cognate ligands.

Given the predominant role of the TNFR family in regulating immunity, this suggests that the evolution of the receptors in this family arose coincident with the evolution of adaptive immunity, also found exclusively in vertebrates. The size of the TNFR superfamily appears to have grown in a large part by gene duplication as many of the TNFR genes are linked to discrete loci reflecting their evolutionary derivation. Perhaps most obvious are those TNFRs found on chromosome (Ch) 12p13 (TNFR1, LT β R, and CD27), which likely underwent duplication and translocation events giving rise to the larger locus of TNFR on Ch 1p36 (TNFR2, HVEM, OX40, CD30, AITR, 4-1BB, and DR3) (Figure 2(a)).

Most members of the TNFRSF have ligands related to TNF; however, some other TNFRs, including neurotrophin p75

receptor (p75 or NGFR), TROY (or Taj), RELT, and DR6, bind ligands unrelated to TNF (Figure 2(b)). The p75 neurotrophin receptor is a functional component within the p75/NgR1/LINGO-1 complex, and can bind to all four neurotrophins: nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4). The p75 subunit serves as a signal transducing receptor for the complex, and its signaling plays an important role in the development of sensory neurons and the repair of nerve damage. Recently, TROY, another orphan TNFRSF, was identified as an alternative component of the p75/NgR1/LINGO-1 complex. TROY is capable of forming a functional receptor complex with NgR1 and LINGO-1 to activate RhoA guanosine triphosphatase (GTPase) in the presence of myelin inhibitors. The herpesvirus entry mediator (HVEM; TNFRSF14) not only binds two TNF-related ligands, LIGHT and LT α , but also engages the Ig superfamily members, B and T lymphocyte attenuator (BTLA) and CD160. HVEM can serve as both a receptor and a ligand.

Another subtle branch in the TNFR family tree are those receptors that engage BAFF, the B-cell survival factor, and related ligands APRIL and TWEAK (Figure 2(b)). These TNFR superfamily members have a single CRD and in the case of BAFFR only two disulfide bonds. Functional divergence is evident in the role some TNFRs play in distinct physiological processes including bone formation (Osteoprotegerin-RANK-RANKL/TRANCE), ectodermal (Ectodermal dysplasin EDA-EDAR), and angiogenesis (TWEAK-Fn14).

Expression

Expression patterns of the receptors are complex. Several members of the TNFR superfamily are expressed on cells of the immune system; for example, BAFFR expression is exclusive to B lymphocytes. Other receptors are found in hair follicles (e.g., EDAR and TROY) or the nervous system (e.g., NGFR); yet others have very broad constitutive tissue expression patterns, such as TNFR1 and LT β R. The inducible expression of some TNFRs, such as OX40, reflects the constitutive expression of its ligand, OX40L. For example, TNFR2 is absent on naive T cells

Figure 1 Structural features of TNFR family. Space-filling model of a trimeric TNFR1 ligand, LT α , as it would exist as a membrane-anchored ligand, and a single TNFR1 rotated 180° to reveal contact residues. Also shown are crystal structures of the cytoplasmic DD found in some TNFRs and the TRAF that interacts with TNFR-containing TRAF-binding sites.

but is rapidly upregulated upon activation of T cells. By contrast, HVEM is highly expressed on naive T cells, but shows diminished expression upon T-cell activation. Regulation of receptor expression can also be achieved through the generation of soluble receptors; soluble TNFRs can be generated by proteolytic processing (CD27, CD30, CD40, TNFR1, and TNFR2), alternative splicing of membrane forms (Fas and 4-1BB), or encoded in the genome without a transmembrane region (OPG, DcR3, and TRAIL-R3).

Ligand Binding

TNF ligands are characterized as type II (intracellular N terminus) transmembrane proteins containing a TNF homology domain (THD) in their C terminus (Figure 1). The THD assembles into trimeric proteins; in most cases, the ligands form homotrimers, but LT α and LT β form heterotrimers, and so does BAFF and APRIL. The TNF ligands are active in their membrane forms where cell-to-cell contact is required to initiate signaling; however, some ligands can be proteolytically cleaved from the surface creating soluble cytokines that affect cells distally.

The TNF ligand superfamily currently includes 20 proteins that are able to pair off with one or more TNF receptors. In fact, some ligands display overlapping receptor recognition; for example, LIGHT and LT α 1 β 2 bind LT β R; LT α and LIGHT bind HVEM; BAFF binds TACI, BCMA, and BAFFR. The ligand-receptor pairing seems promiscuous, although comparative studies using mice deficient in a specific TNF ligand or receptor suggest that each cytokine-receptor system has a unique role in physiology.

Furthermore, some TNFRSF members have non-TNF superfamily interacting partners. For example, HVEM interacts with

BTLA or CD160, and these interactions are important for the modulation of coinhibitory signaling for T-cell activation and proliferation (Figure 3(a)). In contrast to the TNFSF ligands, BTLA and CD160 are a type I transmembrane protein with a single Ig-type domain. Interestingly, both BTLA and CD160 also serve as activating ligands for HVEM. Binding of BTLA or CD160 to the first CRD region (CRD1) of HVEM induced HVEM-dependent NF- κ B activation, demonstrating bidirectional signaling between HVEM and BTLA in cells interacting *in trans*. In addition, BTLA and CD160 can self-associate as homo-oligomeric complex on the cell surface, providing a basis for oligomerizing HVEM that leads to TRAF molecules recruitment and activation of NF- κ B RelA. These results highlight the complexity of the TNF-Ig superfamily co-signaling networks.

HVEM interacts with BTLA, CD160, or HSV gD *in cis* within the same membrane, *cis* interactions (Figure 3(b)). The HVEM-BTLA/CD160/gD *cis*-complexes may play important roles in modulating signal transduction among immune cells. Flow cytometric analysis demonstrated that *cis*-association between HVEM and BTLA is the predominant complex expressed on the surface of naive human and mouse T cells, and the formation of HVEM-BTLA *cis*-complex inhibited HVEM-dependent NF- κ B activation. Furthermore, the HVEM-BTLA/CD160/gD *cis*-complex competitively inhibits HVEM *trans*-signaling by all its cellular ligands, providing a mechanism maintaining T cell homeostasis.

TNFR Signaling

Each TNF-related ligand has three receptor binding sites that can cluster together two or three cell-surface receptors, juxtapositioning the cytoplasmic tails of the receptors to initiate signal transduction. Recruitment of specialized signaling molecules (adaptors) to the cytoplasmic domain occurs following receptor clustering. Propagation of TNFR signals occurs through two distinct classes of cytoplasmic adaptor proteins: TRAF or DD molecules.

TRAF-Dependent Signaling

There are six numerically named TRAF proteins (TRAF1–6) that were discovered based on their functions in TNFR-induced signaling; however, TRAF6 and TRAF3 are also key players in signal transduction initiated by the interleukin-1 receptor and the toll-like receptor (TLR) superfamily. TRAF adaptor proteins are a small family of RING finger proteins that play a crucial role in propagating signal transduction leading to the activation of latent transcription factors (Figure 1). The RING domains of TRAF are characteristic of ubiquitin E3 ligases, which has been convincingly demonstrated for TRAF6 and TRAF2. The other TRAF may modify the enzymatic and substrate specificity of the ubiquitination reaction. TRAF can bind directly to the cytoplasmic tails of ligated TNFR. The binding site found in CD40 or the LT β R is a peptide sequence, PXQXI/S or IPEEGD, that fits into a groove in the TRAF homology domain. The binding site in TRAF accommodates a variety of motifs. TNFRs with a DD bind TRAF indirectly via other adaptor proteins, such as TNFR-associated DD (TRADD).

Figure 2 The TNF–TNFR superfamily grouped on the basis of chromosome (Ch) localization of TNFRs. (a) TNFR and TNF ligands are shown with arrows connecting ligand–receptor pairs. CRDs are shown as small ovals. DD is denoted as a rectangular box in the cytoplasmic tail of appropriate receptors. The signaling and effector functions induced by either DD-containing or TRAF-binding TNFR are shown. The panel (b) is the same as (a), with remaining TNFRs grouped on the basis of chromosome localization and ligand binding. Reproduced from Ware CF (2003) The TNF Superfamily. *Cytokine Growth Factor Review* 14(3–4): 181–184.

In the best-studied scenario, TRAF2, TRAF3, and cIAP, another E3 ligase, form a complex that is required to limit the enzyme, NF- κ B-inducing kinase (NIK), in the cell. All three proteins are required to ubiquitinate NIK leading to its continued degradation. The activation of TNFR halts the action of this multisubunit ubiquitin E3 ligase, which allows NIK to accumulate and propagate signaling to IKK α . Functionally, binding of TRAF to TNFR culminates in the activation of transcription factors that act to regulate gene expression. For example, NF- κ B is a small family of latent transcription factors that induces the expression of a large variety of genes involved in inflammatory and immune responses (Figure 4). Two distinct forms of NF- κ B are recognized: NF- κ B1 (RelA, p65) and NF- κ B2 (p100/p52), and each pair with itself or other proteins

(e.g., p50, RelB, and cRel) that form active transcription factors. NF- κ B1 is held in the cytosol by an inhibitor protein (I κ B) while an inhibitory domain controls the cytosolic localization of NF- κ B2. The inhibitory proteins are phosphorylated, ubiquitinated, and degraded in response to activation signals coming from diverse sources that all target the I κ B protein kinase complex (IKK).

Degradation of the inhibitor allows NF- κ B to localize to the nucleus and activate transcription. The NF- κ B1 and B2 pathways induce distinct sets of genes: NF- κ B1 regulates the expression of proinflammatory chemokines and adhesion molecules, while the NF- κ B2 pathway controls the expression of distinct chemokines and cytokines involved in lymphoid organogenesis. BAFFR is only able to activate the NF- κ B2

Figure 3 Schematic illustrations of molecular interactions between HVEM and its ligands. (a) Canonical and unconventional ligands of HVEM. LIGHT and LT α are positive regulators and the canonical ligands of HVEM. Ligation of LIGHT or LT α to HVEM activates HVEM-dependent NF- κ B signaling. BTLA, CD160, and HSV gD serve as unconventional ligands for HVEM. Ligation of CD160 or gD to HVEM induces NF- κ B activation. Bidirectional signaling occurs between HVEM and BTLA. HVEM-mediated BTLA signaling induces tyrosine phosphorylation of the ITIM in BTLA, providing an inhibitory signal to T cells. BTLA, CD160, and gD bind HVEM at the CRD1, but LIGHT and LT α interact with HVEM at the CRD2 and 3. The binding of gD to HVEM blocks HVEM binding to LIGHT or BTLA (not shown in diagram). (b) Formation of HVEM-BTLA/CD160/gD *cis*-complexes. *Cis*-interaction between HVEM, BTLA, CD160, and HSV gD inhibits HVEM binding to its ligands *in trans*.

pathway, suggesting that this pathway is crucial for the expression of survival genes specifically important for B lymphocytes. By contrast, TNFR1 is unable to activate NF- κ B2, which may account for its strong proinflammatory action.

Death Receptor Signaling

A number of TNFRs, including TNFR1 and Fas, are termed 'death' receptors because of their ability to induce apoptotic cell death. Their cytoplasmic tails contain a region of ~ 80 amino acids that fold into six α -helices, termed the 'DD'. The DD serves as a protein interaction motif to recruit signaling adapters such as FADD, TRADD, and RIP that recruit proteases of the caspase family, caspase 8.

In the simplest scheme known to activate the cell death machinery, the adaptor FADD is recruited to ligated Fas initiating formation of the death-inducing signaling complex (DISC). Procaspase 8 is recruited to the DISC through a second interaction motif contained in FADD, termed the 'death effector domain (DED)', that converts procaspase 8 into an active enzyme that in turn activates downstream effector caspases (e.g., caspase 3) resulting in the cleavage of critical cellular substrates leading to programmed cell death (apoptosis). Similarly, TNFR1 activates apoptosis although it requires the adaptor protein TRADD to facilitate FADD recruitment, and is also able to recruit another adaptor protein RIP that also plays a role in procaspase 8 activation. The DISC is regulated by two forms of another protein known as FLIP, which can switch the

Figure 4 Mechanisms of signaling by TNFRs. Upon ligation of LT β R, two NF- κ B pathways are induced. The first leads to induction of the NF- κ B1 pathway and the activation of IKK β and RelA, which control expression of inflammatory genes. The second pathway results in the activation of NF- κ B2 and the processing of p100 to p52 following the activation of NIK and IKK α , leading to the transcription of genes implicated in secondary lymphoid organogenesis and homeostasis. BAFFR only activates the NF- κ B2 pathway, whereas TNFR1 only activates the NF- κ B1 pathway. TNFR1 also contains a DD to signal caspase activation and apoptosis.

DISC between activating caspases or NF- κ B, which in turn regulates genes that block apoptosis, such as the inhibitors of apoptosis (IAP) that promote cell survival.

Effector Functions of the TNFR Family

Despite similarities in structure and signaling mechanisms, TNFRs function in diverse, and often opposing, roles in immune physiology. As discussed above, several reasons that explain their functional diversity include differences in ligand binding, tissue and cellular expression, regulation of expression, and association with signaling adaptor proteins.

Inflammation

A role for TNF family members in host defense and inflammation was first appreciated when it was realized that TNF is identical to a factor termed 'cachectin', a protein known to cause fever and wasting. Inflammatory cells, such as macrophages, induce TNF when specialized innate immune receptors called TLR recognize molecular patterns on microbial pathogens. Binding of TNF to its receptors, TNFR1 or TNFR2, induces a variety of molecules that are crucial for initiating the acute inflammatory response. For example, TNF signaling induces increased expression of adhesion molecules on endothelial cells and secretion of chemokines to promote inflammatory cell migration to the site of infection. TNF induces nitric oxide synthetase producing NO, a diffusible gas with profound relaxing effects on the cardiovascular system. TNF can also activate macrophages and neutrophils to increase their phagocytic capacity and their ability to secrete tissue-degrading enzymes into tissues. Although inflammation is crucial to prevent

infection, it must also be minimized after the pathogenic challenge subsides in order to prevent uncontrolled damage to fragile host tissues. As such, uncontrolled TNF signaling can cause chronic inflammation and wasting, or acutely released septic shock. Drugs that block TNF signaling, such as soluble TNFR decoy receptors, have been developed to prevent inflammatory diseases such as rheumatoid arthritis.

Apoptosis

Cell death by apoptosis is one of the major functions of DD-containing TNFRs. Fas, for example, mediates cell death for varied purposes. First, Fas and its ligand FasL cooperate as major effectors, along with the perforin/granzyme pathway, to trigger killing of pathogen-infected cells by cytotoxic T lymphocytes (CTLs) or by natural killer (NK) cells. In a second context, Fas is required to eliminate excessive CTLs and other effector cells. Fas is induced on long-term antigen-activated lymphocytes to elicit their removal and minimize the excessive expansion of T lymphocytes that can occur in response to T-cell activation in the space-restricted lymphoid environment. In fact, two naturally occurring mutations in mice encoding the gene *lymphoproliferative disorder (lpr)*, *lpr* or *lpr^{cg}*, that affect the expression or the biological activity of the Fas receptor, respectively, demonstrate the important role of Fas in lymphocyte homeostasis. Both of these mutant mice develop an autoimmune phenotype characterized by massive lymphadenopathy, splenomegaly, and autoantibody production.

Cell Survival

BAFFR, BCMA, and TACI are predominantly expressed on B cells and represent a good example of TNFRs that play a role in cell survival. All three receptors bind the TNF-related ligand

BAFF, produced by macrophages and dendritic cells, while BCMA and TACI can also bind the related ligand APRIL. BAFF is required in the maintenance and differentiation of mature B cells in peripheral tissues by supporting B-cell survival and maturation presumably through activation of anti-apoptotic genes. The mechanism for enhanced B-cell survival by BAFF may be partly due to the stimulation of the pro-survival protein bcl-2 and a decrease in the expression of the pro-apoptotic factors. A crucial role for BAFF in BAFF-mediated B-cell survival is evidenced by the fact that neither BCMA- nor TACI-deficient mice have defects in B-cell maturation, whereas A/WySnJ mice, containing a naturally occurring mutation in BAFFR, show defects in B cell maturation. Overexpression of BAFF in mice can result in autoimmune symptoms; similarly, patients with systemic lupus erythematosus (SLE), rheumatoid arthritis, and Sjogren's syndrome show elevated levels of BAFF in the blood. Other TNFRs also play roles in the survival and development of various tissues including the TRANCE system in bone, EDAR in ectodermal tissues, and NGFR in neurons.

Co-stimulation

T-lymphocyte activation is also regulated by several TNFRs where they act as costimulatory signals to positively or negatively influence the proliferation of antigen-stimulated T cells. OX40, CD27, 4-1BB, and HVEM, expressed on CD4⁺ and CD8⁺ T cells, promote T-cell proliferation and cytokine production in response to their respective ligands expressed on dendritic cells. For example, mice deficient in the OX40–OX40L interaction show impaired T-cell proliferative capabilities and cytokine production in response to viruses such as lymphocytic choriomeningitis virus (LCMV) or influenza virus, and the ability to generate or sustain memory T cells is diminished. HVEM through interaction with BTLA or CD160 limits naive T-cell activation and dendritic cell differentiation. Thus, TNFR family members can contribute to immune tolerance.

In B cells, CD40 is a prominent costimulatory receptor where it interacts with its ligand, CD40L, expressed in T cells to initiate T-cell-dependent B-cell antibody responses. Mutations in CD40 or its ligand affect a number of immune functions including Ig class switching; in humans, X-linked hyper-IgM syndrome is due to defects in CD40L structure and function manifesting as an inability to switch IgM to IgG classes.

Organogenesis and Development

A number of TNFRs play roles in the organization of tissues. The lymphotoxin system mediated by LT β R, and its ligand LT $\alpha\beta$, plays a crucial role in lymph node development. Mice deficient in either receptor or ligand completely lack lymph nodes and Peyer's patches. RANK and its ligand RANKL mediate osteoclast differentiation and therefore are important for maintaining normal bone homeostasis. Osteoporosis, a condition of bone thinning, can be caused by overexpression of the soluble RANKL decoy receptor, OPG, which is induced by estrogen and prevents normal bone formation. RANK–RANKL signaling also supports the development of mammary gland

alveolar buds important for lactation, and consequently an absence of RANK induces accelerated apoptosis of mammary epithelial precursors. In fact, mice or humans with deficiencies in EDAR or EDA lack primary hair follicles and sweat glands. NT p75 receptor (p75 or NGFR) is important for the development of sensory neurons; acting alone it induces apoptosis, but upon association with other NGF receptors it mediates the differentiation and survival of neurons. p75-deficient mice develop cutaneous sensorineuronal defects.

Viral Targeting of TNFR

Since several TNFRs and their ligands play a crucial role in mediating immune defenses against invading pathogens and control death and survival fates for cells, it is not surprising that viruses have evolved mechanisms that directly disrupt communication mediated by the TNF family in order to subvert immune effector mechanisms. In fact, viruses, when viewed collectively, have targeted virtually every step of the TNFR signaling pathway, from ligand binding to activation of apoptosis. For example, some viruses, including cytomegalovirus (CMV), herpes simplex virus (HSV), adenovirus, and HIV, induce the expression of FasL and/or TRAIL in the host cell resulting in the probable killing of recruited immune effector cells that express the cognate TNFR death receptor. By contrast, adenovirus downregulates the proapoptotic receptors Fas and TRAILR from the surface of infected cells, thereby preventing the killing of the host cell harboring the virus. Another mechanism of immune evasion employed by poxviruses is the expression of soluble, secreted orthologs of TNFR2 or CD30 that inhibit the interaction of their respective ligands with their cellular receptors. In some cases, viruses and TNFR signaling have been adapted to function cooperatively. For instance, signaling through the LT β R or TNFR1 can prevent the replication of human CMV in fibroblasts without inducing death of the infected cell thereby allowing continued existence of CMV within the host.

Two-Hybrid Protein–Protein Interactions

I Serebriiskii, S Peri, and E A Golemis, Fox Chase Cancer Center, Philadelphia, PA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Bait A term used to describe a DNA-binding domain–protein X fusion, used as a probe in the yeast two-hybrid system (e.g., to screen a library).

Interaction map A schematic showing a network of protein–protein interactions involving one or more proteins of interest.

Interactome A term describing the complete network of protein–protein interactions occurring within an organism.

Prey A term used to describe a transcriptional–activation domain–protein Y fusion, which interacts with a bait.

Two-hybrid system A system in which the interaction of two hybrid proteins (created so that (1) one is a fusion between a DNA-binding domain and protein X, and the second is a fusion between a transcriptional–activation domain and protein Y and (2) X and Y normally interact) in a host organism such as yeast or bacteria causes the activation of one or more easily detectable reporter genes.

The Yeast Two-Hybrid System

The purpose of the two-hybrid system is to provide a genetic system that is capable of scoring the degree of physical interaction between two proteins of interest. To this end, a simple organism such as yeast (*Saccharomyces cerevisiae*) or bacteria (*Escherichia coli*) is engineered such that the interaction of two proteins generates a detectable signal that can be used either to gauge the interaction affinity of two defined proteins or to identify interacting partners for one defined protein by screening an expression library.

The first working example of a two-hybrid system was described in 1989, by Fields and Song. A schematic showing the system paradigm is shown in [Figure 1](#). There are three minimal components for a functioning two-hybrid system. The first component is an expression construct, which synthesizes a first protein of interest as a fusion with a DNA-binding domain (DBD) that binds a short DNA sequence of defined specificity (hybrid 1: frequently termed the ‘bait’). The second component is an expression construct that is used to express either a second defined protein or random clones from a complementary DNA (cDNA) or genomic library, as a fusion with a transcriptional–activation domain (AD) (hybrid 2: frequently termed the ‘prey’). The third component is a reporter cassette, which consists of the DNA-binding site for the first hybrid protein in the context of a minimal promoter, upstream of the coding sequence for an easily scored reporter gene.

For the yeast two-hybrid system to work, there are two preconditions. First, the bait must not be independently functional as a transcriptional activator, such that yeast containing only the bait and the reporter produce no reporter signal. Second, the bait and the prey must be capable of localizing to the cell nucleus; hence, proteins containing signal sequences that efficiently target them to the plasma membrane, or other non-nuclear compartments, are not generally acceptable as baits. However, for proteins that meet these preconditions, the interaction between the bait and the prey brings the transcriptional–AD encoded in the prey to the promoter sequence bound by the bait and activates the transcription of the reporter gene.

A number of groups have built systems that exploit this two-hybrid paradigm in yeast, with several of these systems in common use. The most common DBDs used in these yeast two-hybrid systems are derived from the yeast transcription factor Gal4p or from the bacterial repressor protein LexA. A variety of different AD sequences have been used, among them the AD from Gal4p; the AD from the viral protein VP16; or ‘artificial’ activation sequences encoded from selected fragments of the *E. coli* genome.

Two categories of reporter genes have been used. One category is colorimetric, exemplified by the bacterial lacZ gene. Activation of a lacZ reporter causes yeast colonies to turn blue when plated on medium containing an appropriate substrate, such as X-gal, or can be assessed quantitatively over a dynamic range in excess of 1000-fold in liquid assays using a spectrophotometer or luminometer. The second category of reporter provides an active selection for yeast growth based on the strength of interaction between two proteins. These reporters include genes encoding critical components of yeast metabolic pathways for amino acid synthesis, such that expression of the gene is required for yeast to grow on medium lacking the relevant amino acid (e.g., show an auxotrophic requirement). *HIS3*, required for growth on medium lacking histidine, and *LEU2*, required for growth on medium lacking leucine, have been most commonly used. In general, two-hybrid systems now generally incorporate both colorimetric and auxotrophic reporters, both responsive to the same bait. The use of at least two different reporter genes greatly minimizes the background of false positive interactions in the system, and is essential for library screening applications, wherein excess of 10^6 clones must commonly be analyzed.

Because of the ease of manipulation provided by a genetic system, a yeast two-hybrid system provides a facile means of exploring the interaction of two known partner proteins. This can be done in a predetermined manner, by inserting targeted mutations or deletions into the AD-fused partner, or based on blind selection, for example, by using polymerase chain reaction (PCR) mutagenesis or DNA sonication to develop a randomized library derived from the AD partner. Each mutant derivative can be readily screened for interaction

Figure 1 Schematic of yeast two-hybrid components, and profile of reporter activation. Details of system components are described in the text. Three situations are shown: (1) yeast containing only a bait and two reporters, left; (2) yeast containing bait, prey that does not interact with bait, and reporters, center; and (3) interacting bait and prey, and reporters, right. For each of these three situations, with a typical auxotrophic and colorimetric reporter, six independent colonies of yeast are dotted on plates with selective medium: expected results (growth/no growth, or color/no color) are shown as panel inserts below each schematic.

phenotype. However, the most important use of the yeast two-hybrid system throughout the 1990s has clearly been for the purpose of screening libraries to identify novel interacting partners for proteins of interest. In contrast to other means of identifying interacting proteins, such as biochemical copurification, two-hybrid screening is extremely inexpensive, requiring only engineered strains of yeast and standard microbiological media. It is rapid, providing the potential of completing a screen from start to finish in less than a month. It is effective at yielding returns for a significant percentage of bait proteins (estimated at >50%). Finally, following completion of a successful library screen, plasmids encoding the novel interacting preys can easily be isolated from yeast, avoiding the need for protein sequencing or mass spectrometric analysis required by biochemical methodologies. It is not an exaggeration to note that recent broad adaptation of two-hybrid screening methodologies across the scientific community (with the average number of the two-hybrid related publications in PubMed around ~770 in the years 1999–2009, and up to ~21 000 interactions year⁻¹) was a major contributing source of elucidation for key cell-signaling pathways.

Advanced Applications

Following the validation of the basic two-hybrid system as a useful and reliable tool for study of protein–protein interactions, a number of investigators have explored the potential of the system to study interactions between proteins and partner proteins under additional selective constraints. A first step in this direction was the demonstration that it was possible to identify preys that interacted with baits contingent upon the

modification of the bait by a coexpressed kinase. A second point of interest was the feasibility of identifying proteins that interacted not with a single protein, but with a complex formed by a bait and one or more simultaneously expressed co-baits. A number of investigators have used a two-hybrid approach to identify proteins that interact as constituents of ternary or even quaternary complexes.

Another application of interest has been to use the two-hybrid system to identify and characterize interactions between proteins and nonprotein (e.g., small molecules/drugs and RNAs). In each case, the derivative system has been shown to function at the level of library screening. While screening for RNAs has become relatively broadly adapted as a research tool, screening for drugs that regulate protein–protein interactions was outcompeted by more robust alternative technologies. The two-hybrid system has also been used by a number of investigators to identify peptide aptamers capable of binding and regulating the functions of specific bait proteins. Peptides isolated based on two-hybrid selection have been found capable of regulating diverse functions of their cognate baits, and may provide the basis for design of peptidomimetics or small molecule derivatives of therapeutic value. This is currently an area of active investigation.

Finally, efforts have been made to improve ability of the two-hybrid system for evaluating the selectivity of protein interactions. In these approaches, the two-hybrid system is parallelized, using two discrete sets of baits and reporters within a single strain of yeast. In one example, bait 1 (a fusion to LexA) directs the expression of the *lacZ* and *LEU2* reporters, while bait 2 (a fusion to cI) directs the expression of *gusA* (colorimetric) and *LYS2* (auxotrophic) reporters. In a situation

where a prey initially interacts with both baits 1 and 2, turning on all four reporters, mutagenesis of the prey can be coupled with selective screening for activation of the *lacZ* and *LEU2*, versus the *gusA* and *LYS2*, reporters, providing a convenient means of identifying altered specificity mutants that can be used to deconvolute signal-transduction pathways.

Alternative Two-Hybrid Systems

Although the yeast two-hybrid system has found many useful applications, it has not been appropriate in all cases. Toward the goal of identifying small molecules or mutations that disrupt, rather than permit, protein–protein interactions, a reverse two-hybrid system has been developed. In this system, activation of a reporter gene is toxic, providing selection pressure for clones that have lost protein–protein interactions. For proteins that strongly activate transcription in yeast, and hence cannot be used to create baits, one solution has been to move the two-hybrid components to an RNA polymerase III-based reporter system, eliminating transcriptional activity. Other investigators have generated two-hybrid-like systems in bacteria, where eukaryotic transcriptional-activation sequences are generally ineffective. For proteins that are membrane associated, or cannot efficiently be nuclear localized, several methods for assessing protein interaction at membranes or in the cytoplasm have been developed. In some techniques, interaction of the bait and prey reconstitutes an intracellular signaling pathway (e.g., the Sos and Ras recruitment systems). In another approach, called the split-ubiquitin membrane yeast two-hybrid system, interaction of a bait and prey at the cell membrane results in the reconstitution of functional ubiquitin fused to LexA-VP16 transcription factor, which is subsequently cleaved and migrates to the nucleus, activating standard yeast two-hybrid colorimetric and auxotrophic reporters. This approach combines advantages of membrane-based interaction detection with the ability to use well-validated screening modalities.

Role in Proteomics

Two hybrid protein–protein interaction systems are important elements of strategies to analyze the complete protein–protein interactions of proteomes. To date, extensive protein interaction maps have been constructed for representatives of all major groups of living organisms, including animals, plants, fungi, bacteria, and viruses (as well as virus–host interactions). In the case of model organisms, advances in screening methodologies including low- and high-throughput screening

methods contributed to large-scale identification of binary interactions. Concerted efforts in yeast (*S. cerevisiae*), worm (*Caenorhabditis elegans*), fruit fly (*Drosophila melanogaster*), and *Homo sapiens* revealed tens of thousands of protein–protein interactions. These efforts provide a useful complement to simultaneous efforts to analyze protein interactions using protein complementation assay and tandem affinity purification/mass spectrometry. Among these techniques, each having inherent advantages and constraints, the yeast two-hybrid system appears superior at identifying binary protein–protein interactions for nontransmembrane proteins. Interactions being detected through these methods are being integrated into databases including transcriptional profiles, genetic interaction data, and protein localization data for the same proteins, providing a fundamental tool for the emerging field of systems biology. It is likely that continuing application of the two-hybrid protein–protein interaction will remain a source of scientific insights for many years to come.

Glossary

PAPS 3'-Phosphoadenosine 5'-phosphosulfate, sulfate donor in the sulfate transfer reaction. PAPS has been known to be the activated form of sulfate and acts as cosubstrate for the sulfation of a wide variety of substances, including proteins.

trans-Golgi network The last station of the Golgi complex. This site is a major branching point of vesicular transport and the origin of two principal pathways of protein secretion: the regulated and constitutive pathways.

The O-sulfation of tyrosine residues of membrane and secretory proteins that transit through the secretory pathway of eukaryotic cells is a ubiquitous posttranslational modification conserved in all multicellular organisms. Tyrosine sulfation is catalyzed by tyrosylprotein sulfotransferase (TPST) isoenzymes, which are integral membrane proteins of the *trans*-Golgi network. Tyrosine sulfation has been shown to be important for protein–protein interactions occurring in diverse biological processes, ranging from the receptor binding of regulatory peptides to the interaction of viral envelope proteins with the cell surface.

Tyrosine-Sulfated Proteins

Occurrence

Sulfation is one of the most abundant posttranslational modifications of tyrosine, since up to 1% of the tyrosine residues of total protein in an organism can be sulfated. Tyrosine is the only amino acid residue in proteins known to undergo sulfation. Following the first description of a sulfated-tyrosine residue in a peptide derived from fibrinogen by Bettelheim in 1954, it has been known since 1982 that tyrosine-sulfated proteins occur in all animals, from lower invertebrates up to humans. Tyrosine-sulfated proteins also exist in the plant kingdom, for example, in the green alga *Volvox*, one of the earliest truly multicellular organisms, or in higher plants such as rice. While occurring throughout metazoan evolution, tyrosine-sulfated proteins appear to be absent in unicellular eukaryotes and prokaryotes, implicating this posttranslational modification in some aspect of multicellularity.

In a given animal, tyrosine-sulfated proteins have been observed in all tissues examined. Each tissue appears to contain a characteristic set of tyrosine-sulfated proteins, suggesting that proteins with tissue-specific expression are major targets for tyrosine sulfation. In cell culture, tyrosine sulfation of proteins has been detected in all primary cultures and cell lines investigated, including various secretory cells, epithelial cells, fibroblasts, neuronal cells, and cells of the immune system.

Tyrosine-sulfated proteins can be identified by various methods, including labeling using radioactive sulfate followed by tyrosine sulfate analysis of a given protein. In line with the intracellular localization of TPST in the *trans*-Golgi network

(Figures 1(a) and 1(b)), all known tyrosine-sulfated proteins are either secretory or plasma membrane proteins. Reviews with comprehensive lists of tyrosine-sulfated proteins have been published, and several of these proteins have been shown to play important biological roles.

Structural Determinants of Tyrosine Sulfation

The recognition, by TPST, of the tyrosine residue to be sulfated in a secretory protein or the extracellular domain of a membrane protein requires the presence of certain structural features. These have been deduced from the comparison of identified tyrosine sulfation sites and the *in vitro* tyrosine sulfation of synthetic peptides. Although no strict consensus sequence for tyrosine sulfation exists, all sequences exhibit the presence of acidic amino acid residues in the vicinity, that is, positions -5 (N-terminal) to $+5$ (C-terminal), of the sulfated tyrosine residue. A particularly critical position appears to be amino-terminal (-1) to the tyrosine. Turn-inducing amino acids (P, G) are also frequently present. The few examples of tyrosine-sulfation sites lacking proline and glycine are located near the N- or C-terminus of the protein and/or contain several of the three other amino acid residues (D, S, N) with significant turn-conformational potential. Finally, another characteristic feature common to most identified tyrosine-sulfation sites is the absence of cysteine residues or potential N-glycosylation sites (NXS or NXT) in the vicinity (positions -7 to $+7$). In either case, the presence of a disulfide bridge or N-linked oligosaccharides is likely to prevent sulfation of nearby tyrosine residues due to steric hindrance.

Tyrosylprotein Sulfotransferase (EC 2.8.2.20)

The Tyrosine-Sulfation Reaction

The sulfate transfer reaction to tyrosine residues is catalyzed by TPST, first described in 1983, and used as a sulfate donor, the cosubstrate 3'-phosphoadenosine 5'-phosphosulfate (PAPS) (Figure 1(b)). The transfer is thought to occur in an ordered reaction mechanism that involves the following sequential steps: (1) cosubstrate PAPS binding; (2) substrate binding;

Figure 1 (a) Tyrosine sulfation occurs in the *trans*-Golgi network (TGN). (b) TPST, a type II transmembrane protein, catalyzes the transfer of the sulfate group (boxes) from the co-substrate PAPS to tyrosine residues of secretory proteins and ectodomains of membrane proteins passing through the lumen of the *trans*-Golgi network. (c) The three principal types of tyrosine sulfation-dependent protein-protein interactions (for details, see text).

(3) sulfate transfer; (4) tyrosine-sulfated product release; and (5) PAP release. TPST activity can be detected by incubation of appropriate membrane preparations with [³⁵S]PAPS using either endogenous or exogenous protein substrate. Biologically, tyrosine sulfation appears to be an irreversible event *in vivo* due to the lack of a sulfatase capable of catalyzing the desulfation of tyrosine-sulfated proteins under physiological conditions.

Properties of TPST

TPST is an integral membrane protein residing in the *trans*-Golgi network (Figures 1(a) and 1(b)). The TPST protein can be identified in membrane preparations by modification after substrate cross-linking (MSC) labeling, which is based on the cross-linking of a substrate peptide to TPST followed by intramolecular [³⁵S] sulfate transfer from the cosubstrate PAPS. Various nonionic detergents can be used to solubilize TPST from membranes.

TPST purified from bovine adrenal medulla is a 50–54-kDa sialoglycoprotein with an apparent S-value of 6. Its pH optimum is between 6.0 and 6.5, which is in line with the slightly acidic pH of the *trans*-Golgi network. The catalytic activity of the enzyme, toward endogenously as well as exogenously added proteins, is stimulated by divalent cations (Mg²⁺, Mn²⁺), and fluoride ions are required for maximal activity. The *K_m* for the cosubstrate PAPS is 1.4 μM. Like most sulfo-transferases, TPST is inhibited by PAP. *In vitro*, the activity of the enzyme is also inhibited by certain lipids such as sphingosine, but the physiological relevance of this observation is unknown. Synthetic inhibitors of TPST (with IC₅₀ values of 30–40 μM) have been generated by a combinatorial target-guided ligand assembly technique.

The *K_m* for most peptides (8–13 amino acid residues) with a single tyrosine sulfation site is in the range of 10–100 μM. It is likely that similar values hold true for individual tyrosine-sulfation sites in proteins. Interestingly, *K_m* values for synthetic

substrates containing multiple tyrosine-sulfation sites are considerably lower. Given that several proteins exist with multiple adjacent sulfation sites, for example, cionin, heparin cofactor, and prepro-cholecystokinin, the increased affinity of TPST for such substrates might be of physiological significance, for example, by promoting stoichiometric sulfation. A remarkable example of the sequential sulfation of four tyrosine residues within a short stretch of amino acids is the N-terminal domain of the CC-chemokine receptor 5 (CCR5), which is a coreceptor for HIV.

Molecular Cloning and Membrane Topology of TPST

Distinct TPST isoenzymes, anticipated from the differential substrate specificities of various TPST preparations, exist in the human and mouse genome. Each contains two TPSTs, TPST-1 (see Swiss-Prot Database, Accession No. 060507) and TPST-2 (see Swiss-Prot Database, Accession No. 060704), which were first characterized at the molecular level in 1998. The human *TPST-1* (7q11) and *TPST-2* (22q12.1) genes encode for 370- and 377-amino acid proteins, respectively, that share an overall 65% identity. The murine *tpst* genes are located on chromosome 5, and the corresponding proteins show ~95% identity to their human counterpart. Both TPST isoenzymes are predicted to have a type II membrane topology, with a very short NH₂-terminal cytoplasmic domain (eight residues) and the bulk of the polypeptide, which is responsible for the catalytic activity, being located in the Golgi lumen (see Figure 1). Although overall, TPST isoenzymes display a low degree of amino acid identity to other cytosolic and Golgi-associated sulfotransferases, most of the residues involved in PAPS binding, as deduced from comparison with the crystal structure of estrogen sulfotransferase, are conserved. The luminal domain of either isoenzyme also contains two potential N-glycosylation sites, consistent with presence of N-linked glycans in the TPST protein.

In agreement with the occurrence of tyrosine sulfation in all metazoan species, complementary DNAs (cDNAs) that predict proteins obviously related to mammalian TPSTs are found in various vertebrates and invertebrates, including fish (GenBank Accession No. B1846282), frog (GenBank Accession No. BG815875), chicken (GenBank Accession Nos. BU142429, BU217098), fly (GenBank Accession No. AY124548), and worm (GenBank Accession No. NM_067245).

TPST-1 versus TPST-2

TPST-1 and TPST-2 transcripts are found in all tissues examined, for example, brain, heart, skeletal muscle, gut, kidney, liver, lung, and leukocytes. Although ubiquitously expressed, the tissue distribution of TPST-1 and TPST-2 are not identical. Recombinant TPST-1 and TPST-2 show similar, but not identical, activities toward certain small peptide substrates, consistent with some functional redundancy as well as a certain degree of differential substrate specificity.

TPST-1- and TPST-2-Deficient Mice

TPST-1- and TPST-2-deficient mice, generated by targeted disruption of the *tpst-1* and *tpst-2* genes, also point to functional

redundancy between the two isoenzymes, as either line of knockout mice is viable. Although TPST-1^{-/-} animals appear normal, their body weight is reduced about 5% and an increase in postimplantation fetal death is observed, suggesting that unidentified proteins involved in regulation of body weight and reproductive physiology require tyrosine sulfation for optimal function. TPST-2-deficient mice show a transient delay in growth during postnatal development. In addition, the males, but not females, appear to be infertile. Together, these observations are consistent with the idea that TPST-1 and TPST-2 have distinct, but partially overlapping, physiological roles.

Physiological Function and Medical Relevance

For most tyrosine-sulfated proteins, the physiological function of this posttranslational modification is presently unknown. With regard to the cases in which the biological role of tyrosine sulfation of a particular protein has been elucidated, the common denominator has emerged that tyrosine sulfation promotes extracellular protein-protein interactions. In line with the identification of numerous secretory and plasma membrane proteins that are tyrosine sulfated, paradigmatic examples exist showing that tyrosine sulfation promotes the interaction between (1) a secretory and a plasma membrane protein, (2) two secretory proteins, or (3) two plasma membrane proteins (Figure 1(c)).

The regulatory peptide cholecystokinin is a classical example where tyrosine sulfation of a secretory protein dramatically promotes its interaction with a plasma membrane protein, that is, its cell surface receptor. Thus, sulfated cholecystokinin is 260 times more potent than its unsulfated form. Of the several examples of tyrosine sulfation promoting the interaction between two secretory proteins, the case of the binding of the tyrosine-sulfated blood coagulation factor VIII to von Willebrand factor is particularly intriguing, as it also documents the medical relevance of this posttranslational modification. Humans with a mutation in the critical tyrosine residue of factor VIII that is sulfated and involved in its binding to von Willebrand factor are afflicted with hemophilia A.

An example of tyrosine sulfation promoting the interaction between two plasma membrane proteins is the important role of this posttranslational modification for the high-affinity binding of leukocyte-associated P-selectin glycoprotein ligand (PSGL)-1 to P-selectin on activated endothelial cells. This crucial interaction initiates adhesion of leukocytes to the vascular wall during inflammation. Tyrosine sulfation also occurs in seven-transmembrane-segment chemokine receptors, for example, CCR5. Under physiological conditions, these plasma membrane proteins play a central role in chemokine signaling pathway through G proteins. Remarkably, human and simian immunodeficiency viruses use CCR5 as a co-receptor, together with CD4, to mediate their attachment to the host cell membrane. Specifically, sulfation of tyrosine residues in the CCR5 N-terminal domain has been shown to be critical for the interaction of this protein with human immunodeficiency virus (HIV) envelope glycoprotein gp120, leading to HIV infection. Thus, the design of tyrosine-sulfated peptide competitors – mimicking HIV gp120-binding sites – could turn out to be the basis for new therapeutic compounds that will block HIV

cellular entry. These examples highlight the medical relevance of protein tyrosine sulfation.

Glossary

De-UBLylation Ubiquitin-like protein (UBL) proteases-mediated removal of conjugated UBL from substrate.

E1, E2, E3 Components of UBL conjugation machinery, with nomenclature derived from ubiquitin conjugation pathway. E1 activates UBL; E2 transfers the activated UBL either directly to the substrate or to an E3, which facilitates covalent bond formation between the terminal diglycine motif and acceptor cysteine of the substrate.

UBL-binding motif A protein motif that noncovalently interacts with conjugated UBL. Such interaction confers regulatory function and thus proteins with UBL-binding motif usually act as effectors of UBLylation pathway.

UBLylation The process of protein covalent modification by a specific UBL. For example, SUMOylation and NEDDylation refers to small ubiquitin-like modifier (SUMO)-mediated and neural precursor cell expressed, developmentally down regulated 8 (NEDD8)-mediated covalent modification respectively.

Introduction

Ubiquitin is a posttranslational modifier. The elaborate biochemical machinery for ubiquitin conjugation has its root in various metabolite/cofactor biosynthesis pathways in prokaryotes and is further diversified to attach ubiquitin-like proteins (UBLs) to their targets. Since the identification of interferon-induced 15-kDa protein (Isg15) as the first UBL in 1992, now there are 11 proteins (small ubiquitin-like modifier (SUMO)1, SUMO2, SUMO3, SUMO4, neural precursor cell expressed, developmentally down regulated 8 (NEDD8), Isg15, Atg8, Atg12, Fat10, Ufm1, and Urm1) in the eukaryotic UBL family. These proteins are defined not by sequence similarity but instead by the presence of a conserved β -grasp fold in their structures. A β -grasp fold is an ancient structure that can be found in *Escherichia Coli* cofactor synthesis proteins MoaD and ThiS. It consists of a stranded beta-sheet, an alpha-helix, and a C-terminally extruded tail with a di-glycine motif, which is crucial for covalent conjugation to substrates. A general scheme for UBL modification involves activation, conjugation, ligation, and deconjugation (see [Figure 1](#)). Some UBLs are capable of forming polymeric branching chains just like ubiquitin. Monomeric and polymeric chains of UBL add an extensive interacting surface to the target molecule and therefore are capable of regulating enzymatic activity, protein complex formation, subcellular distribution, and protein stability.

Experimentally verified UBL targets are involved in diverse cellular processes that can be found in every facet of cell biology. With the multitude of UBL signals, a specialized set of protein domains co-evolves with UBLs to specifically recognize UBL-modified proteins and ensures the UBL codes are correctly interpreted. Proteins with such UBL-binding domains may bind to monomeric/polymeric UBLs with various affinities and, therefore, render UBL-mediated protein complex formation highly flexible in response to different biological cues. Intriguingly, UBLs not only exist as standalone proteins but are also found as structural domains in more complex polypeptides. They act like built-in UBL modification to mediate interaction with UBL-binding domains and generally are not subject to enzymatic processing and cleavage.

Activation, Conjugation, Ligation, and Deconjugation

The dynamics of UBL attachment is regulated by four groups of enzymes: E1, the activating enzyme; E2, the conjugation enzyme; E3, the ligation enzyme; and UBL proteases (see [Table 1](#)). Most UBLs are synthesized as inactive precursors. They first have to be processed by specific UBL proteases or hydrolases to remove C-terminal tail and expose the di-glycine motif. E1 will adenylate the exposed glycine at the cost of adenosine triphosphate (ATP) hydrolysis. This is the only

Figure 1 A general scheme for protein UBLylation dynamics.

step that consumes ATP in the UBL modification reaction. The UBL~adenosine monophosphate (AMP) intermediate is then attacked by a cysteine in the E1 catalytic core to form a high-energy thioester bond with the UBL. Following that, E1~UBL binds to an E2 through an ubiquitin-fold domain on E1 and transfers UBL to the catalytic cysteine of E2. While E2~UBL in many cases is sufficient to relay UBL to the substrate, the ligation is always facilitated by an E3 which brings in the substrate, binds to E2~UBL intermediate, and catalyzes the isopeptide bond formation between the carboxyl group of terminal glycine on UBL and the ϵ -amino group of acceptor lysine on the substrate. Similar to ubiquitin E3, really interesting new gene (RING) domain or homologous to the E6-associated protein carboxyl terminus (HECT) domain in many UBL E3s are the major effectors for ligating UBL.

The transfer of UBL between loaded E1, E2, and E3 is driven by the release of inorganic pyrophosphate and AMP. In its free status, E1 has low affinity for E2. The binding to E2 only takes place with E1~UBL intermediate, which allosterically inhibits E2 binding to E3. On the other hand, free E3 has a high

affinity only for loaded E2 but not for free one. The differential affinity between free/UBL-loaded enzymes and its downstream cognates account for the unidirectional transfer of UBL between E1, E2, and E3.

To deconjugate UBL from its substrate, a UBL protease will bind the UBL-modified substrate and catalytic cysteine of the protease will attack the isopeptide bond to cleave UBL from substrate and form a protease~UBL intermediate. At the end, hydrolysis of the thioester bond will release UBL from the protease. Most UBL-modified substrates only account for a small portion of the steady-state pool, and it is generally accepted that UBL proteases are a crucial factor in determining steady-state level of UBL-modified substrate.

Small Ubiquitin-Like Modifier

SUMOs are the best characterized UBL. Since its discovery in 1996, hundreds of proteins have been experimentally identified to be modified by SUMO. SUMO genes are highly

conserved among yeasts, worms, flies, and vertebrates. Their homologs are also found in plants and archae. There are four SUMO genes in the mammalian genome. SUMO1 is a nuclear protein with 101 amino acids and shares 18% sequence similarity to ubiquitin. SUMO2 and SUMO3, which are 97% identical before their C-terminal di-glycine motif, are also nuclear proteins and only share 50% sequence similarity with SUMO1. While SUMO1, SUMO2, and SUMO3 are ubiquitously expressed, SUMO4 is preferentially expressed in immune cells and pancreatic islets. Although genetic evidence suggests that SUMO4 M55V polymorphism confers susceptibility to type I diabetes, it remains controversial whether or not SUMO4 can be processed into mature UBL and conjugate target proteins. SUMO1, SUMO2, and SUMO3 attach to their targets as a monomer. In addition, SUMO2 and SUMO3 are found to form branching chains just like ubiquitin through Lys11 linkage. SUMO1 also forms polymeric chain via Lys7, Lys16, and Lys17 *in vitro*. However, there is no concrete evidence for polymeric SUMO1 chains *in vivo*. Instead, SUMO1 may conjugate to polymeric SUMO2/3 chain and act as a cap to stop its extension.

The E1 for SUMO conjugation is a heterodimer composed of Aos1 and Uba2. Endogenous regulation of SUMO E1 is not yet understood. However, an avian adenovirus protein Gam1 targets Aos1 for ubiquitination and degradation through its SOCS domain via Cul2/5-Elongin B/C-Roc1 ubiquitin E3 ligase complex. As a consequence, Uba2 also degrades and the loss of functional E1 leads to impaired global SUMOylation. Ubc9 is the only E2 for SUMO. Sequence analysis of the first few SUMO substrates has revealed a common SUMO acceptor motif ψ -K-X-D/E, where ψ stands for aromatic amino acids and X stands for any amino acid. Over a decade, the rule is confirmed in many other molecules and is the only established acceptor consensus among UBLs. However, not all lysines in this motif are SUMO acceptors, and in many cases SUMO conjugates to a cryptic lysine that cannot be predicted based on protein-sequence analysis.

The E3 for SUMO features the presence of RING-type plant homeo domain (PHD) finger. The largest collection of SUMO E3 is the protein inhibitors of activated STAT (signal transducers and activators of transcription) (PIAS) family members, in addition to Pc2, RanBP2, Mms21, Rhes, and Topors. Interestingly, the PHD finger of Trim25 can function as an intramolecular SUMO E3. Although Aos1/Uba2 and Ubc9 are sufficient for SUMOylation, SUMO E3s facilitate the reaction, result in functional compartmentalization, and usually are the targets for regulating SUMOylation balance.

A functional SUMO pathway is essential for life. Unbiased analysis of heat-shocked cells suggests that SUMO regulates transcriptional repression, chromatin regulation, DNA damage response, lipid metabolism, and cell-cycle progression. How does SUMO achieve such versatility? The first clue comes from the long list of SUMO targets. These proteins tend to cluster in functionally relevant categories, and therefore imply the crucial regulatory role of SUMO in those biological processes. In addition to its far-reaching footprints, molecular consequences of protein SUMOylation also diversify. SUMOylation may render stronger interaction with DNA and thus promote chromatin binding. SUMOylation may alter the components of the transcriptional complex and switch on/off transcription by

differential recruitment of transcriptional cofactors. SUMOylation also interacts with other posttranslational modifications. For example, nuclear factor of kappa light polypeptide gene enhancer in B-cells inhibitor, alpha (I κ B α) can be modified by SUMO at Lys21, which is also an ubiquitin acceptor. Lys21 SUMOylation is sufficient to inhibit tumor necrosis factor- α (TNF α)-induced ubiquitination and degradation of I κ B α , and thus blocks subsequent nuclear factor kappa B (NF κ B) activation. Another example comes from the SUMOylation of core histones H2B, H3, and H4 in yeast. SUMOylation of H2B and H4 reversely correlate to acetylation at galactokinase (GAL1) promoters during altered carbon supply. Meanwhile both ubc9 and Δ siz1 Δ siz2 mutants, which cannot undergo normal SUMOylation due to the lack of either E2 or E3, display enhanced acetylation of gene-associated H3. On the contrary, SUMOylation can be attenuated by phosphorylation. In the case of Elk1, mitogen-activated protein (MAP) kinase-mediated phosphorylation of Ser383 blocks SUMOylation, which is required for its maximal transcriptional repression.

In addition to covalent modification, SUMOs are also capable of noncovalent interaction with SUMO interaction motif (SIM). SIM, with a consensus of (V/I/L)-(V/I/L)-X-(V/I/L) or (V/I/L)-X-(V/I/L)-(V/I/L) and usually a flanking acidic residue, binds to the second β -strand and the first α -helix of SUMO. The terminal di-glycine of SUMO is not involved in SUMO-SIM interaction. Such interaction is one to two orders stronger than that between ubiquitin and ubiquitin-binding domains. SIM-containing protein binds and exerts its function depending on the SUMOylation status of its partner, and in this sense the SUMO-SIM pair provides a specific decoding mechanism of protein SUMOylation marks. A good example is RING finger protein 4 (RNF4), a SUMO-targeted ubiquitin ligase. It has four SIMs and one RING-type PHD finger which catalyzes ubiquitin conjugation. RNF4 only binds promyelocytic leukemia protein (PML), a crucial protein in the pathogenesis of acute promyelocytic leukemia, after arsenic-induced SUMOylation. As a consequence, PML is ubiquitinated by RNF4 on its poly-SUMO tags and degrades in a proteasome-dependent manner. This is believed to be one of the therapeutic mechanisms of arsenic in treating acute promyelocytic leukemia.

Considering the large number of SUMO targets, it is surprising that six isopeptidase – sentrin/SUMO specific proteases (SENP) – in the mammalian genome are sufficient for keeping proper SUMO status of hundreds of proteins. SENPs are cysteine peptidase and all of them contain a C48 protease domain in the C-terminal. The six SENPs can be divided into three subfamilies according to the substrate specificity, sequence homology, and cellular localization. SENP1 and SENP2 are mammalian ortholog of the yeast Ulp1 and both readily deconjugate SUMO1 and SUMO2. SENP3 and SENP5 are nucleolar proteins with a preference for deconjugating SUMO2/3. SENP6 and SENP7 have a split C48 protease domain in the C-terminal. While the deSUMOylating activities of these two enzymes are controversial, they are capable of editing polymeric SUMO chains. Early embryonic lethality of mice deficient of either SENP1 or SENP2 suggests that these SENPs perform nonredundant functions. Accessibility of SENP to its substrate may dictate paralog-selective SUMOylation in cells. For example, SUMO1-conjugated RanGAP1 forms a more stable complex with nucleoporin RanBP2 compared to its SUMO2 conjugates and this

prevents binding of the yeast SENP Ulp1. As a result, RanGAP1 is preferentially SUMOylated by SUMO1 *in vivo*.

Neural Precursor Cell Expressed, Developmentally Downregulated 8

NEDD8, also known as related to ubiquitin 1, or Rub1, in budding yeast is the closest kin of ubiquitin in the UBL family (60% sequence identity). The 81-amino-acid protein was identified in 1992 with a subtraction cloning approach from mouse-neural precursor cell complementary DNA (cDNA) library and its function as a UBL was first characterized in 1997 in our laboratory. It is ubiquitously expressed, evolutionarily conserved, and is essential for cell viability. NEDD8 is a crucial regulator of ubiquitin E3 ligase complexes. Dysregulated NEDDylation has been observed in tumors and neurodegenerative diseases, implying its correlation with the onset and progression of human diseases.

NEDD8 is synthesized as inactive precursor with a stretch of four glycines in the C-terminus. NEDD8 protease SENP8 (Den1) and hydrolase UchL3 are both capable of exposing the Gly76 for conjugation. The E1 for NEDD8, like the SUMO E1, is a heterodimer composed of Uba3 and Nae1. Despite the similarity, NEDD8 conjugating machinery is devoted for processing NEDD8 but not ubiquitin. Several mechanisms account for such specificity. First of all, Uba3/Nae1 is capable of discriminating NEDD8 from ubiquitin due to a strategically positioned basic residue in the UBL binding pocket of Uba3, which repels Arg72 in ubiquitin but not Ala72 in NEDD8. Second, the NEDD8 E2 Ubc12 has a unique N-terminal sequence that is required for Uba3/Nae1 binding, which prevents mischarging of ubiquitin-specific E2s to NEDD8 E1. In addition, Ubc12 has a smaller cysteine-binding pocket and a unique groove which accommodates N-terminal extrusion of NEDD8. These structural features allow Ubc12 to discriminate NEDD8 from ubiquitin. Recently, Ube2F is found to be the second NEDD8 E2. Ubc12 and Ube2F form a complex with different E3 (Rbx1 and Rbx2, respectively), neddylation distinct substrates, and result in selective ubiquitin E3 ligase complexes activation.

Rbx1, a common component of Skp1-Cul1-F-box-protein (SCF) and Elongin B/C, Cullen-2, VHL-containing (ECV) ubiquitin E3 ligase complexes, is the first reported NEDD8 E3. It harbors a RING-finger domain which not only approximates ubiquitin E2 to the substrate but also promotes cullin neddylation *in vitro*. The second NEDD8 E3, Dcn1, contains a potentiating neddylation (PONY) domain that is required for neddylation activity *in vitro* and *in vivo*. Dcn1 may act as a scaffold to facilitate interaction between substrate and NEDD8-charged Ubc12. It is interesting that *in vitro* reconstitution of NEDDylation requires the presence of both Dcn1 and Rbx1, which indicates potential synergy between the two molecules. In addition to Dcn1 and Rbx1, ubiquitin E3 ligases Mdm2 and Cbl are also reported to promote NEDDylation in an E3-like fashion.

All of the cullin family members are NEDD8 substrates. Cullins are structural scaffold for Cullin-RING ubiquitin ligase, and neddylation of cullins are essential to bring in E2 to promote the ubiquitination and degradation of their cognate

target cyclins, which are crucial regulators for cell cycle progression. Human Cul-1 is a major component of SCF ubiquitin E3 ligase that catalyzes the ubiquitination of I κ B α , β -catenin, and p27^{Kip1}; NEDDylation of Cul-1 is essential for the ubiquitin ligase activity. Molecular consequences of NEDDylation may involve changes in protein conformation. In the case of SCF, NEDDylation of Cul-1 exposes the RING finger of Rbx1 and therefore facilitates ubiquitin ligation to the proximal substrate. In another case, NEDDylation of cullins allosterically inhibits the binding of Cdn1, which is an inhibitor of cullin E3 complex, and activates SCF ubiquitin ligase. NEDDylation can also recruit new binding partners. For example, epidermal growth factor receptor (EGFR) is a noncullin NEDD8 substrate. It can be neddylation by Ubc12-loaded Cbl at the cytoplasmic domain upon ligand binding, and then recruits Cbl precomplexed with ubiquitin E2 UbcH7 to EGFR. Subsequent ubiquitylation and degradation of EGFR ensures rapid receptor desensitization. Additional noncullin NEDD8 substrates include p53, p73, Mdm2, VHL, L11, and other ribosomal proteins. NEDD8 has been reported to form polymeric chains *in vitro*. The significance of poly-NEDD8 chain *in vivo* remains unknown.

COP9 signalosome (CSN) is the best-characterized NEDD8 isopeptidase. CSN is a protein complex that interacts with Cul-1-containing SCF-type E3 ubiquitin ligases and promotes the cleavage of NEDD8 from neddylation Cul-1. The Jab1/Mpr/Pad1 N-terminal (MPN) domain metalloenzyme motif in Csn5 subunit is responsible for the de-neddylation activity of CSN. Thus, CSN binds to SCF-type E3 ubiquitin ligases and probably regulates their activity through the de-neddylation of conjugated Cul-1. SENP8/Den1, a cysteine protease in the SENP family, is another NEDD8-specific isopeptidase. Unlike CSN, SENP8/Den1 is weak in de-neddylation cullins. SENP8/Den1 deletion results in accumulation of NEDD8 conjugates; removing one allele of SENP8/Den1 genetically counteracts the developmental lethality in NEDD8 hypomorphic mutants. Therefore, SENP8/Den1 may act as the major de-neddylase for noncullin NEDD8 substrates. In addition to CSN and Den1, NEDD8 conjugates can also be cleaved by ubiquitin-NEDD8 dual specific proteases such as Usp21, ataxin-3, PfUch54, Uch-L3, and Uch-L1.

Regulation of NEDD8 pathway is more complicated than simply keeping balanced conjugation/deconjugation. Nub1 (NEDD8 ultimate buster 1), a 66-kDa NEDD8-interacting protein with a N-terminal ubiquitin-like domain, has been shown to direct NEDD8 and its conjugates to 19S subunit of proteasome and results in their degradation. NEDD8 pathway can also be manipulated pharmacologically. MLN4924 is a suicide inhibitor for NEDD8 E1 Nae1/Uba3 heterodimer and suppresses tumor cell growth. It is currently under phase II clinical trial for treating acute myelocytic leukemia and may become the first UBL-targeting compound for human cancer treatment.

Interferon-Induced 15-kDa Protein

Isg15 was first identified as a 15-kDa protein induced by interferon treatment in 1979. The gene actually encodes a 17-kDa protein with two tandem ubiquitin-like domains and was found to form high molecular weight conjugates in 1992.

Unlike SUMO and NEDD8, Isg15 is only present in vertebrates and these homologs share limited sequence similarity. Isg15 protein is detected in lymphoid tissues, striated and smooth muscles, receptive uterine endometrium, epithelial cells, and neurons. In mammals, Isg15 is an important regulator of antiviral defense. Despite the lack of a classical signal peptide and a membrane receptor, Isg15 is secreted and may act in an autocrine/paracrine fashion to modulate interferon production from CD3+ lymphocytes and subsequent NK cell proliferation and activation. While Isg15 knockout mice are viable and fertile, they are more vulnerable to viral infections. Interestingly, the antiviral property seems to be dependent on its UBL property rather than its cytokine property since reconstitution of nonconjugatable Isg15 cannot rescue the virus susceptibility.

Uba7 is the only E1 dedicated to Isg15 activation. This protein is a monomeric E1. It has been reported that influenza virus protein NS1B specifically interacts with Uba7 and inhibits its E1 activity. The cognate E2 for Uba7 is UbcH8. There are only a few E3 that have been identified as Isg15 E3 including Herc5 and Efp. The fact that Isg15, Uba7, and UbcH8 are all upregulated after interferon treatment may explain enhanced protein ISGylation after type I interferon (IFN- α and IFN- β) stimulation. It is noteworthy that some cell lines (such as K562 and 293T cells) do not respond to interferons with detectable protein ISGylation. In the case of K562 cells, it is ascribed to the defective expression of Uba7. So far Ubp43 is the only one Isg15-specific protease that has been identified. An *in vitro* screen of ubiquitin-specific proteases has identified Usp13 as a dual-specificity protease that is capable of processing ubiquitin and Isg15. However, *in vivo* validation of this finding is still pending.

Experimentally verified Isg15 targets include Stat1, Jak1, Erk1, PKR, Mx1, RIG-1, Ubc13, and influenza protein NS1A. ISGylation of these proteins do not lead to proteosomal degradation nor does it lead to altered subcellular localization. ISGylation of an ubiquitin E2 Ubc13 blocks its ability to form thioester bond with ubiquitin and therefore abolishes subsequent Lys63-linked polyubiquitination. Enhanced ISGylation of Jak1 and Stat1 in Ubp43-deficient bone marrow cells are associated with persistent Stat1 phosphorylation and enhanced expression of interferon-stimulated genes. As a result, bone marrow cells die soon after interferon treatment. However, whether ISGylation of Jak1/Stat1 accounts for the phenotype observed in Ubp43-deficient mice was challenged by the observation that compound deletion of Isg15/Ubp43 does not rescue the Ubp43 deletion phenotypes.

Atg8 and Atg12

Autophagy is a tightly regulated catabolic process that turns over proteins and organelles with lysosomal degradation machinery in a eukaryote cell. There are approximately 30 proteins for the autophagy pathway in yeast. Among them are two UBLs, Atg8 and Atg12, and their conjugation system components. Both UBL pathways are required for efficient autophagy as deletion of any component leads to autophagy defect. Atg8 and Atg12 share little sequence similarity. However, structurally they both have ubiquitin-like folds. Both

Atg12 and Atg8 conjugation systems are conserved in mammalian cells and they act in a similar manner.

Atg12 is synthesized as mature UBL and does not require to be processed prior to E1 activation. The E1 for Atg12 is Atg7, which forms a thioester bond between its Cys507 and Gly186 of Atg12. Atg10 is the only E2 for Atg12 conjugation pathway. The transfer of Atg12 from Atg10 to its sole substrate Atg5 does not need an E3 and is constitutively active. Atg12–Atg5 conjugate localizes to the outer membrane of and promotes the expansion of autophagosome. Atg12 conjugation seems to be irreversible since there is no isopeptidase to cleave Atg12 from Atg5. Atg12-modified Atg5 interacts with coiled coil protein Atg16 and forms multimeric complex to direct Atg8-PE to tightly associate with the expanding autophagosome membrane.

The other UBL, Atg8, modifies phosphatidylethanolamine (PE, a lipid moiety on autophagosome membrane). It is synthesized as a precursor as most UBLs do. The protease Atg4 cleaves and exposes Gly116 of Atg8 so that it can conjugate to Cys 507 of Atg7 (the same E1 and the same cysteine residue as used in Atg12 conjugation pathway) for activation. Atg7 is a noncanonical E1 because, unlike the ubiquitin and SUMO E1, it forms a homodimer and the resulting homodimeric adenylation domains are likely to bind two UBL molecules simultaneously. This is more close to the prokaryotic E1 antecedent MoeB and ThiF. Atg7 also stands out among UBL E1s due to its capability to activate two unrelated UBL, Atg12 and Atg8, and specifically transfer these UBL to their cognate E2. The structural basis for such duality is not known. Atg8 is then transferred to the E2 Atg3 and then forms an amide bond between PE and Atg8. Atg12 interacts with Atg3 and such interaction allows Atg12–Atg5 complex to promote Atg8 modification of PE. Although Atg12–Atg5, in this sense, acts like an E3 but the complex lacks HECT or RING domains which is the hallmark of most UBL E3. Atg8–PE is the structural determinant of autophagosome membrane expansion, and quantitative fluorimetry analysis suggests a positive correlation between Atg8 abundance and the size of autophagosome. It is also capable of joining the ends of expanding lipid bilayer and finalizes autophagosome formation. On completion of autophagosome formation, Atg8-PE will be cleaved by the protease Atg4. Atg4-mediated recycling of Atg8 is crucial for efficient autophagy since reintroduction of processed Atg8 into Δ Atg4 mutant is capable of binding to PE, but cannot rescue hampered autophagosome formation upon nutrient depletion.

Fat10

Fat10, also known as diubiquitin or ubiquitin D, is originally identified as a UBL-encoding gene in the human leukocyte antigen F (HLA-F) locus. The molecule consists of two ubiquitin-like domains in tandem arrangement and bears a conserved di-glycine motif at its C-terminus. It is expressed in mature B cells, dendritic cells, B lymphoblasts, thymus, tonsil, pancreatic islets, mammary gland epithelia, and small intestine. Fat10 is capable of covalent conjugation as all UBLs do, but the conjugation machinery is poorly characterized. Fat10 is synthesized in mature form and forms thioester bond with Uba6, which is a monomeric E1 and also surprisingly activates ubiquitin. Uba6 does not load Fat10 onto its cognate ubiquitin E2

including Ubc3, Ubc5, Ubc13, and E2-25K. The structural basis for such specificity is unknown. The other members of the Fat10 pathway, including E2, E3, protease, and the substrate are yet to be identified.

Current knowledge on the function of Fat10 is limited. Like Isg15, Fat10 is an interferon-responsive gene and it can also be induced by tumor necrosis factor alpha. Strong upregulation of Fat10 has been observed in hepatocellular carcinoma, colorectal carcinoma, and HIV-infected renal tubular epithelial cells, which might be due to the proinflammatory microenvironment in these samples. Although Fat10 knockout mice are viable, fertile, and grossly normal, they are more vulnerable to endotoxin-induced sepsis. These evidences imply that Fat10 is involved in innate immunity.

The best-characterized molecular property of Fat10 is its role in the control of protein quantity and quality. Linearly fused Fat10 serves as an ubiquitin-independent degron (the amino acid sequence that tags the protein for degradation) to promote protein degradation at a comparable kinetics to their ubiquitin-fused counterparts. Fat10-dependent degradation is not affected in cells defective in ubiquitin activation, or in cells expressing lysine-mutated Fat10 which prevents ubiquitin conjugation. Noncovalent interaction between Fat10 and NUB1L, which associates with the 26S proteasome, is required for Fat10-fused protein to be processed by proteasome

in vitro and greatly facilitates the degradation of Fat10 monomer and its conjugates *in vivo*. It is interesting to note that both Fat10 and NUB1L are interferon-responsive genes and overexpression of Fat10 but not its conjugation-defective mutant leads to apoptosis. Fat10 also promotes aggresome formation in case of proteasome failure through its interaction with histone deacetylase (HDAC6), which is involved in the transportation of ubiquitylated misfolded protein to aggresome for sequestration and removal. Other functions of Fat10 include its roles in regulating mitosis through its interaction with mitotic spindle assembly checkpoint protein (MAD2) and mediating NF- κ B signal transduction.

Glossary

Proteolysis/degradation Hydrolysis of a protein which is a heteropolymer of amino acids to short peptides, which contain a few amino acids, and/or to single amino acids.

Ubiquitination Covalent modification of a protein by the small protein ubiquitin.

In the ubiquitin system, a target substrate is modified by ubiquitin or a ubiquitin-like protein. In most cases, proteins are modified by multiple moieties of ubiquitin, generating a polyubiquitin chain. This modification leads to their degradation by the 26S proteasome complex. Modification by a single moiety of ubiquitin can target proteins for degradation in the lysosome/vacuole. Modification by ubiquitin-like proteins serves nonproteolytic functions. Conjugation of ubiquitin is carried out by a modular cascade of enzymes, specific to each substrate. Ubiquitination of cellular proteins is a highly complex, temporally controlled, and tightly regulated process that targets in a specific manner thousands of cellular proteins and plays major roles in a variety of basic pathways, such as cell division, differentiation, and quality control. Not surprisingly, aberrations in the system underlie the pathogenesis of many diseases, certain malignancies, and neurodegenerative disorders. Mechanism-based drugs are currently being developed.

Mechanisms of Ubiquitination and Degradation

Ubiquitination

Degradation of a protein via the ubiquitin–proteasome pathway involves two discrete and successive steps: (1) tagging of the substrate by covalent attachment of multiple ubiquitin molecules; and (2) degradation of the tagged protein by the 26S proteasome complex with release of free and reusable ubiquitin. This last process is mediated by ubiquitin-recycling isopeptidases (deubiquitinating enzymes). Conjugation of ubiquitin, a highly evolutionarily conserved 76-residue polypeptide, to the protein substrate proceeds via a three-step cascade mechanism. Initially, the ubiquitin-activating enzyme, E1, activates ubiquitin in an adenosine triphosphate-requiring reaction to generate a high-energy thiol ester intermediate, E1-S ~ ubiquitin. One of several E2 enzymes (ubiquitin-carrier proteins or ubiquitin-conjugating enzymes) transfers the activated ubiquitin from E1, via an additional high-energy thiol ester intermediate, E2-S ~ ubiquitin, to the substrate that is specifically bound to a member of the ubiquitin-protein ligase family, E3. There are a number of different classes of E3 enzymes. For the homologous to the E6-AP C-terminus (HECT) domain E3s, the ubiquitin is transferred once again from the E2 enzyme to an active site Cys residue on the E3, to generate a third high-energy thiol ester intermediate,

ubiquitin-S ~ E3, prior to its transfer to the ligase-bound substrate. RING finger-containing E3s catalyze direct transfer of the activated ubiquitin moiety to the E3-bound substrate.

E3s catalyze the last step in the conjugation process: covalent attachment of ubiquitin to the substrate. The ubiquitin molecule is generally transferred to an ϵ -NH₂ group of an internal lysine residue in the substrate to generate a covalent isopeptide bond. In some cases, however, ubiquitin is conjugated to the N-terminal amino group of the substrate. By successively adding activated ubiquitin moieties to internal lysine residues on the previously conjugated ubiquitin molecule, a polyubiquitin chain is synthesized. The chain is recognized by the downstream 26S proteasome complex. Thus, E3s play a key role in the ubiquitin-mediated proteolytic cascade since they serve as the specific recognition factors of the system. In certain cases the first ubiquitin moiety is conjugated to the substrate by one E3, while chain elongation is catalyzed by a different ligase often termed E4. Modification by a single moiety of ubiquitin is catalyzed via an identical mechanism and set of enzymes. The specific enzymes that catalyze modification by ubiquitin-like proteins are somewhat different, though they utilize a similar mechanism.

Degradation

Degradation of polyubiquitinated substrates is carried out by a large protease complex, the 26S proteasome that does not recognize nonmodified substrates. In one established case, that of the polyamine-synthesizing enzyme ornithine decarboxylase, the proteasome recognizes and degrades the substrate without prior ubiquitination. The proteasome is a multicatalytic protease that degrades polyubiquitinated proteins to short peptides. It is composed of two subcomplexes: a 20S core particle (CP) that carries the catalytic activity and a regulatory 19S regulatory particle (RP). The 20S CP is a barrel-shaped structure composed of four stacked rings, two identical outer α -rings and two identical inner β -rings. The eukaryotic α - and β -rings are composed each of seven distinct subunits, giving the 20S complex the general structure of $\alpha_{1-7}\beta_{1-7}\beta_{1-7}\alpha_{1-7}$. The catalytic sites are localized to some of the β -subunits. Each extremity of the 20S barrel can be capped by a 19S RP. One important function of the 19S RP is to recognize ubiquitinated proteins and other potential substrates of the proteasome.

A ubiquitin-binding subunit of the 19S RP has indeed been identified; however, its importance and mode of action have not been discerned. A second function of the 19S RP is to open an orifice in the α -ring that will allow entry of the substrate into the proteolytic chamber. Also, since a folded protein would not be able to fit through the narrow proteasomal channel, it is assumed that the 19S particle unfolds substrates and inserts them into the 20S CP. Both the channel-opening function and the unfolding of the substrate require metabolic energy, and indeed, the 19S RP contains six different adenosine triphosphatase subunits. Following degradation of the substrate, short peptides derived from the substrate are released, as well as reusable ubiquitin. Proteasomal degradation is not always complete. In some cases, the proteasome, rather than completely destroying its target, processes the ubiquitinated substrate precisely, releasing a truncated product. In the case of the nuclear factor kappa B (NF- κ B) transcriptional regulator, an active subunit (p50 or p52) is thus released from a longer inactive precursor (p105 or p100). For a general scheme of the ubiquitin system and its multiple functions, see Figure 1.

Substrate Recognition

A major unresolved question is: How does the system achieve its high specificity and selectivity? Why are certain proteins extremely stable in the cell, while others are extremely short-lived? Why are certain proteins degraded only at a particular time point during the cell cycle or only following specific

extracellular stimuli, yet they are stable under most other conditions? It appears that specificity of the ubiquitin system is determined by two distinct and unrelated groups of proteins: E3s and ancillary proteins. First, within the ubiquitin system, substrates must be specifically recognized by an appropriate E3 as a prerequisite to their ubiquitination. In most cases, however, substrates are not recognized in a constitutive manner, and in some cases they are not recognized directly by the E3. In some instances, the E3 must be switched on by undergoing posttranslational modification in order to yield an active form that recognizes the substrate. In many other cases, it is the substrate that must undergo a certain change that renders it susceptible for recognition. The stability of additional proteins depends on association with ancillary proteins such as molecular chaperones that act as recognition elements in *trans* and serve as a link to the appropriate ligase. Others, such as certain transcription factors, have to dissociate from the specific DNA sequence to which they bind in order to be recognized by the system. Stability of yet other proteins depends on oligomerization. Thus, in addition to the E3s themselves, modifying enzymes (such as kinases), ancillary proteins, or DNA sequences to which substrates bind also play an important role in the recognition process.

Functions and Substrates of the Ubiquitin System

Ubiquitin-mediated proteolysis of a variety of cellular proteins plays an important role in many basic cellular processes.

Figure 1 The ubiquitin system for protein modification. Ubiquitin (Ub) is activated by the three enzymes E1, E2, and E3, and the active ubiquitin moiety is transferred to the target substrate (red). Substrates can be either modified by a polyubiquitin chain (a) and targeted to the 26S proteasome complex for degradation (or processing), or modified by a single ubiquitin moiety, monoubiquitinated (b) and targeted to other organelles such as the lysosome (wherein it is degraded). Ubiquitin-like proteins (Ubl) are activated by E1, E2, and E3, which are similar but not identical to the enzymes that activate ubiquitin. Modification by Ubl (c) serves a variety of nonproteolytic functions such as routing of proteins to subcellular organelles (e.g., nucleus), protecting them from ubiquitination, or activating them.

Among these are regulation of cell cycle and division, differentiation and development, involvement in the cellular response to stress and extracellular effectors, morphogenesis of neuronal networks, modulation of cell-surface receptors, ion channels and the secretory pathway, DNA repair, transcriptional regulation, transcriptional silencing, long-term memory, circadian rhythms, regulation of the immune and inflammatory responses, and biogenesis of organelles. The list of cellular proteins that are targeted by ubiquitin is growing rapidly. Among them are cell-cycle regulators such as cyclins, cyclin-dependent kinase inhibitors, and proteins involved in sister chromatid separation, tumor suppressors, transcriptional activators, and their inhibitors. Cell-surface receptors and endoplasmic reticulum (ER) proteins are also targeted by the system. Finally, mutated and denatured/misfolded proteins are recognized specifically and removed efficiently. In this capacity, the system is a key player in the cellular quality control and defense mechanisms. The products of the proteasome can play an important role in the immune response. In the case of degradation of foreign proteins – such as those of viral origin – the resulting short peptides are presented by major histocompatibility complex class I molecules to the cytotoxic T cell that lyse the presenting cell.

Regulation of the Ubiquitin System

The ubiquitin–proteasome pathway can be regulated at the level of ubiquitination or at the level of proteasome activity. Since conjugation and proteasomal degradation is required for a multitude of cellular functions, regulation must be delicately and specifically tuned. In a few cases, general rather than specific, components of the pathway can be modulated by physiological signals. For example, upregulation of the pathway is observed during massive degradation of skeletal muscle proteins that occurs under normal fasting, but also under pathological conditions such as cancer cachexia, severe sepsis, metabolic acidosis, or following denervation. In most cases, however, regulation is specific and the target substrates are recognized by specific ligases that bind to defined motifs. The targeting motif can be a single amino acid residue (e.g., the N-terminal residue) or a sequence (the destruction box in cyclins) or a domain (such as a hydrophobic patch) that is not normally exposed. In other cases, the motif is a posttranslational modification such as phosphorylation that is generated in response to cell needs or external signals. Phosphorylation can occur either on the substrate or on the ligase.

Ubiquitin-Like Proteins

Both enzymes and substrates of the ubiquitin system have been found to be modified by ubiquitin-like proteins. Modification by ubiquitin-like proteins occurs only once. In the case of enzymes, modification affects their activity. For example, the modification by the ubiquitin-like protein NEDD8 enhances the activity of a certain class of E3 ligases. Conjugation of NEDD8 to one of the components of the ligase complex (Cullin) increases its affinity to other components of the conjugation machinery. In the case of substrates, modification can

affect their availability to the ubiquitination/degradation machinery and consequently cellular stability. For example, in the case of I κ B ζ , the inhibitor of the transcriptional regulator NF- κ B, modification by small ubiquitin-like modifier (SUMO)-1 was shown to protect the substrate from ubiquitination. In a completely different case, SUMOylation of RanGAP1 targets the protein to its final subcellular destination in the nuclear pore complex.

Ubiquitination and Pathogenesis of Human Diseases

Diseases

While inactivation of a major enzyme such as E1 is obviously lethal, mutations or acquired changes in enzymes or in recognition motifs in substrates that do not affect vital pathways or that affect the involved process only partially may result in a broad array of diseases. The pathological states associated with the ubiquitin system can be classified into two groups: those that result from (1) loss of function – mutation in a ubiquitin system enzyme or target substrate that results in stabilization of certain proteins and (2) gain of function – abnormal or accelerated degradation of the protein target.

Alterations in ubiquitination and deubiquitination reactions have been directly implicated in the etiology of many malignancies. In general, cancers can result from stabilization of oncoproteins, or destabilization of tumor-suppressor gene products. Some of the natural substrates for degradation by the proteasome are oncoproteins that, if not properly removed from the cell, can promote cancer. For instance, ubiquitin targets N-myc, c-myc, c-fos, c-jun, Src, and the adenovirus E1A proteins. Destabilization of tumor-suppressor proteins, such as p53 and p27, has also been implicated in the pathogenesis of malignancies.

In one fascinating case, that of uterine cervical carcinoma, the level of the tumor-suppressor protein p53 is extremely low. Most of these malignancies are caused by high-risk strains of the human papillomavirus (HPV). Detailed studies have shown that the suppressor is targeted for ubiquitin-mediated degradation by the virally encoded oncoprotein E6. Degradation is mediated by the native HECT domain E3 enzyme E6-AP, where E6 serves as an ancillary protein that allows recognition of p53 *in trans*. E6-AP will not recognize p53 in the absence of E6. E6 associates with both the ubiquitin ligase and the target substrate and brings them to the necessary proximity that is assumed to allow catalysis of conjugation to occur. Removal of the suppressor by the oncoprotein is probably an important mechanism used by the virus to transform cells.

Accumulation of ubiquitin conjugates and/or inclusion bodies associated with ubiquitin, proteasome, and certain disease-characteristic proteins have been reported in a broad array of chronic neurodegenerative diseases, such as the neurofibrillary tangles of Alzheimer's disease, brainstem Lewy bodies – the neuropathological hallmark in Parkinson's disease, and nuclear inclusions in CAG repeat expansion (poly-glutamine expansion) disorders such as Huntington's disease. However, in all these cases, a direct pathogenetic linkage to aberrations in the ubiquitin system has not been established. One factor that complicates the establishment of such linkage is the realization that many of these diseases, such as Alzheimer's and

Parkinson's, are not defined clinical entities, but rather syndromes with different etiologies. Accumulation of ubiquitin conjugates in Lewy inclusion bodies in many of these cases may be secondary, and reflects unsuccessful attempts by the ubiquitin and proteasomal machineries to remove damaged/abnormal proteins. While the initial hypothesis was that inclusion bodies are generated because of the inherent tendency of the abnormal proteins to associate with one another and aggregate, it is now thought that the process may be more complex and involves active cellular machineries, including inhibition of the ubiquitin system by the aggregated proteins. This aggregation of brain proteins into defined lesions is emerging as a common, but poorly understood mechanistic theme in many sporadic and hereditary neurodegenerative disorders.

The case of Parkinson's disease highlights the complexity of the involvement of the ubiquitin system in the pathogenesis of neurodegeneration. Aberrations in several proteins such as mutations in α -synuclein, an important neuronal protein, or in the deubiquitinating enzyme UCH-L1, have been described that link the ubiquitin system to the pathogenesis of the disease. One important player in the pathogenesis of Parkinson's disease is Parkin which is a RING-finger E3. Mutations in the gene appear to be responsible for the pathogenesis of autosomal recessive juvenile parkinsonism (AR-JP), one of the most common familial forms of Parkinson's disease. Parkin ubiquitinates and promotes the degradation of several substrates. It is possible that aberration in the degradation of one of these substrates that leads to its accumulation is neurotoxic and underlies the pathogenesis of AR-JP.

The cystic fibrosis (CF) gene encodes the CF transmembrane regulator (CFTR) that is a chloride channel. Only a small fraction of the protein matures to the cell surface, whereas most of it is degraded from the ER by the ubiquitin system prior to its maturation. One frequent mutation in the channel is $\Delta F508$. The mutation leads to an autosomal recessive inherited multisystem disorder characterized by chronic obstruction of airways and severe maldigestion due to exocrine pancreatic dysfunction. Despite normal ion channel function, CFTR $\Delta F508$ does not reach the cell surface at all, and is retained in the ER from which it is degraded. It is possible that the rapid and efficient degradation results in complete lack of

cell-surface expression of the $\Delta F508$ protein, and therefore contributes to the pathogenesis of the disease.

Drug Development

Because of the central role the ubiquitin system plays in such a broad array of basic cellular processes, development of drugs that modulate the activity of the system may be difficult. Inhibition of enzymes common to the entire pathway, such as the proteasome, may affect many processes nonspecifically, although a narrow window between beneficial effects and toxicity can be identified for a short-term treatment. Recent experimental evidence strongly suggests that such inhibitors may indeed be beneficial in certain pathologies, such as in multiple myeloma, a malignancy that affects the bone marrow.

A completely different approach to drug development can be the development of small molecules that interfere with the activity of specific E3s. For example, peptides that bind specifically to HPV-E6 can prevent its association with p53 and interfere with its targeting by E6-AP. Such peptides were able to induce p53 in HPV-transformed cells with subsequent reversal of certain malignant characteristics and induction of apoptosis.

Glossary

Base substitution mutation A change in DNA in which one DNA base is replaced with another. A purine substituted with a purine or a pyrimidine substituted with a pyrimidine are examples of transition mutations. A purine substituted with a pyrimidine or vice versa are examples of transversion mutations.

Co-protease A protein that facilitates the proteolytic action of another enzyme. For example, RecA facilitates the autocleavage of LexA to initiate the SOS response.

Frameshift mutation A change in DNA that alters the reading frame, which involves either deletion or insertion of one or more nucleotides. Addition or insertion of any number of nucleotides that is not a multiple of three will result in frameshift mutagenesis.

Homologous recombination RecA of *Escherichia coli* binds to ssDNA and aligns it with a homologous sequence in double-stranded DNA, therefore promoting the exchange of the double-stranded DNA piece to the single-stranded DNA and a new double strand is formed.

Lesion Damaged DNA, usually a modified base resulting from chemical or environmental stressors.

Mutagenesis Formation of a mutation, or the insertion of an incorrect base opposite a base or lesion in the template DNA strand.

Translesion synthesis (TLS) The process of copying damaged DNA templates. Depending on the nature of the damage and the polymerase utilized, TLS may be accurate or error prone.

Weigle reactivation Survival of UV-exposed λ bacteriophage is increased when the infected *E. coli* is pre-irradiated with UV light.

The SOS Response: Transcriptional Regulation of Pol V

The SOS response is a cellular response to DNA damage and is named after the universal distress call SOS – ‘save our ship’ or ‘save our souls.’ Upon DNA damage, the replicative DNA polymerase, pol III, is generally unable to copy noncanonical or damaged DNA and so becomes uncoupled from DNA helicase. This leads to the formation of a region of single-stranded DNA (ssDNA), on which the RecA protein polymerizes, a process that requires adenosine triphosphate (ATP), to form the RecA/ssDNA nucleoprotein filament, also known as RecA* (Figure 1). The RecA protein has multiple roles in responding to DNA damage, including in a DNA repair pathway known as homologous recombination repair. The *lexA* gene product, LexA, serves as the repressor of the SOS genes, binding to a consensus regulatory sequence known as the ‘SOS box’. LexA is a dimeric protein consisting of a DNA-binding domain and a protease domain. RecA*, acting as a co-protease, facilitates autocleavage of LexA, a reaction which is carried out by the catalytic dyad Ser119–Lys156 of LexA, at its Ala84–Gly85 bond. LexA cleavage prevents dimerization and results in the exposure of a protease targeting signal on LexA, which leads to degradation of LexA and therefore derepression of the SOS genes. In the SOS response, the expression of at least 57 genes is induced, allowing for the expression of the *umuC* and *umuD* genes among many others, including those involved in DNA repair and regulation of the cell cycle. The *umuD* and *umuC* genes are organized in an operon that is regulated by a single LexA box located upstream of the *umuD* gene. The start codon of *umuC* overlaps by 1 nt with the stop codon of *umuD*. The expression of these genes is coordinately regulated;

however, the *umuC* gene product is present at lower steady-state levels than the *umuD* gene products. UmuC is present at about 15 molecules per cell prior to SOS induction. Once SOS is induced and UmuC is generated, this number increases to about 200 molecules per cell. UmuD is present at about 200 molecules per cell and increases to approximately 2400 molecules per cell after SOS induction.

Not all genes are expressed to their highest levels at the moment that LexA is cleaved. The *umuDC* genes are expressed about 20–50 min after LexA cleavage. This delay gives time for other, accurate modes of DNA damage repair, such as nucleotide excision repair, to occur before potentially mutagenic translesion synthesis (TLS) is utilized. Full-length UmuD together with UmuC have a role in delaying the resumption of DNA replication after DNA damage. This function is beneficial to the cell in that it allows time for accurate repair processes to take place. UmuD and UmuC at elevated levels cause a cold sensitive growth phenotype that is not well understood, but appears to correlate with inhibition of DNA replication. Full-length UmuD also prevents mutagenesis, as cells expressing a noncleavable variant of UmuD are nonmutable.

Regulation of UmuC Function by Cleavage of UmuD

Similar to the mechanism of LexA cleavage, UmuD₂ undergoes slow autocleavage via interaction with RecA* to give UmuD'₂ (Figure 2). The exceptionally slow cleavage reaction of UmuD₂ is likely important for the cell to delay the use of a potentially mutagenic process until necessary. The UmuD'₂ form of the protein is required for UmuC to be active in TLS, forming pol V

Figure 1 (a) When RecA binds to single-stranded DNA (ssDNA) in the presence of ATP, it is activated as RecA*. (b) This activated form of RecA serves as a coprotease in the autocleavage of LexA, which is the repressor of the SOS genes. Once LexA is cleaved, at least 57 SOS genes are expressed, and proteins such as UmuC and UmuD are translated.

as the UmuD'₂C complex. The UmuD active site is composed of the Ser60–Lys97 catalytic dyad, and cleaves between residues Cys24 and Gly25. Mixing a noncleavable UmuD active site variant with a noncleavable UmuD cleavage site variant results in UmuD cleavage, demonstrating that UmuD'₂ can cleave in *trans*. That is, the active site of one monomer cleaves the arm of its partner in the dimer. There is currently no high-resolution structure of UmuD'₂. The solution NMR and X-ray structures of UmuD'₂ that have been determined are quite different, suggesting that UmuD'₂ is a highly flexible and dynamic protein. This also seems to be true of full-length UmuD'₂. Although UmuD'₂ is a very tight dimer, it readily exchanges monomers, so that if two different UmuD'₂ variants are combined, they form heterodimers. The UmuDD' heterodimer has been found to be the most stable dimeric form, which has implications for protein half-life in the cell, discussed below.

umuDC Role in Mutagenesis

Mutagenesis and its effects were studied long before UmuD'₂C was determined to be a DNA polymerase. In 1953, Jean Weigle discovered that survival of UV-irradiated bacteriophage λ increased if the *Escherichia coli* host cell that it infected was also UV-irradiated prior to infection. This phenomenon, named

Figure 2 (a) After expression, UmuD'₂ undergoes an autocleavage reaction facilitated by RecA*, similar to that of LexA. UmuD'₂ is cleaved to form UmuD'₂, the active form in pol V. UmuD'₂C is then formed, which is the active DNA polymerase V in *E. coli*. (b) The X-ray crystal structure of UmuD'₂, with each monomer shown as green or yellow and the active site Ser and Lys residues highlighted as blue and red spheres, respectively (PDB ID: 1AY9).

Weigle reactivation, was strong evidence that there was a pathway in *E. coli* that responds to DNA damaged by UV radiation. In 1967, Evelyn Witkin suggested that this hypothesized pathway may be controlled by a repressor that is inactivated by UV radiation. Witkin also suggested that the repressor becomes active once again when the pathway is complete. Miroslav Radman named this pathway that is induced by DNA damage the 'SOS repair' pathway, later known as the SOS response. The SOS response and in particular the functions of the *umuDC* genes were characterized genetically for well over 20 years, before it was discovered that UmuD'₂C is a translesion DNA polymerase.

The *umuDC* genes were so named because *E. coli* strains lacking these genes were unmutable when treated with UV light or other DNA damaging agents. For years the SOS response was referred to as a 'mutagenic repair' response, because while enhanced cell survival was observed, such survival came at the cost of mutations. It is now appreciated that mutagenesis is an active process facilitated by the TLS activity of UmuD'₂C. Mutations generated by the *umuDC* gene products may confer a selective advantage on cells and, therefore, may be a driving force in bacterial evolution. Deletion of the *umuDC* genes actually has little effect on the ability of *E. coli* to survive most DNA damaging treatments. Remarkably, cells harboring a noncleavable variant of UmuD (Ser60Ala), besides being nonmutable, are extremely sensitive to UV light. Thus, the presence of only full-length UmuD'₂ (with UmuC) that cannot be converted to UmuD'₂ is more detrimental to a cell than the complete absence of the *umuDC* genes. This is thought to be related to the functions of UmuD'₂ and UmuC in inhibiting DNA replication, but the exact mechanism is unknown.

The Discovery of Pol V

Originally, it was thought that UmuC and UmuD were accessory factors that somehow modified the replicative polymerase pol III to allow it to bypass lesions in DNA. The difficulty in purifying active, soluble UmuC alone or in complex with UmuD₂ contributed to the persistence of this model. In 1999, the purification of UmuC was reported by two different labs. Zvi Livneh and researchers purified UmuC fused to maltose binding protein (MBP), while Myron Goodman and researchers, working with the group of Roger Woodgate, purified UmuC in a complex with UmuD₂. This allowed the Livneh group to determine that UmuC alone possesses polymerase, but not TLS activity, and that the presence of UmuD₂ is required for UmuC to be active in TLS. Both groups used different DNA substrates as well, with the Livneh group using circular, gapped DNA while the Goodman group used linear DNA. Differences in protein preparation and the substrates used likely led to differing conclusions about the importance in TLS of accessory proteins such as single-stranded DNA-binding protein (SSB), the β processivity clamp, and the γ clamp loader, as well as the role of RecA in these reactions.

Mechanism of Translesion Synthesis by Pol V

It was originally thought that a RecA/ssDNA nucleoprotein filament was necessary for TLS by pol V. It is also clear that a stable RecA filament on ssDNA would serve as a steric block and not permit synthesis by pol V, so it was proposed that pol V removes RecA from the DNA template to allow TLS. However, it was soon discovered that RecA could stimulate pol V under conditions that were not suitable for filament formation. In addition to its roles in SOS induction and UmuD cleavage, RecA has another role in TLS, namely, in the direct stimulation of pol V. RecA, paired with a nucleotide cofactor such as ATP, stimulates TLS by pol V without the presence of the nucleoprotein filament at the TLS site. The pol V mutasome (pol V Mut) consists of pol V (UmuD₂C), RecA, and ATP, and is the active form of pol V. It has been observed that a filament is required to activate RecA, so it is proposed that the RecA/ssDNA nucleoprotein filament transfers a RecA monomer and an ATP cofactor from the 3' end of the filament to UmuD₂C. In addition to the pol V mutasome, interactions with the β clamp stimulate pol V activity and SSB enhances TLS *in vitro*.

The current model of TLS holds that the replicative DNA polymerase encounters a lesion and is unable to copy past it (Figure 3). The formation of a RecA/ssDNA nucleoprotein filament may facilitate targeting of pol V to lesions, although there are many unanswered questions about how TLS polymerases are recruited to damaged DNA, if indeed they are, and the mechanism of polymerase switching at sites of DNA damage. Pol V synthesizes a TLS patch opposite and past the lesion. This patch must be large enough so that when the replicative DNA polymerase resumes synthesis, its proofreading exonuclease activity is not activated by the presence of the lesion. If the TLS patch is too small, the replicative DNA polymerase could become stalled at the lesion in a futile

Figure 3 Upon DNA damage, the *E. coli* replicative DNA polymerase III (pol III) cannot continue replication. The polymerase stalls (a), causing RecA to polymerize on the single-stranded DNA (b). Polymerase V (pol V) is induced by the SOS response and is able to bypass the lesion (c). Once pol V bypasses the lesion, it continues for about 6–8 nt and then dissociates, allowing pol III to resume replication of the DNA (d).

cycle of nucleotide insertion and excision. Pol V needs to synthesize at least 5 nt past the lesion to allow pol III to resume efficient replication.

Specificity, Fidelity, and Processivity of Pol V

Pol V is specific for bypass of UV photoproducts such as thymine–thymine (T–T) *cis-syn* cyclobutane pyrimidine dimers (CPDs) and T–T (6–4) photoproducts, as well as abasic sites (Figure 4). Pol V inserts two A bases opposite T–T CPDs, and so is accurate when copying that lesion. However, pol V is prone to inserting guanine (G) opposite the 3' T of T–T (6–4) photoproducts. This is considered the mutagenic signature of pol V due to the fact that normally, adenine (A) is inserted across from T. Moreover, this correlates with the mutation spectrum observed *in vivo* in SOS mutagenesis. When copying abasic sites, pol V inserts mostly A, following the general 'A-rule' of DNA polymerases, as well as G. Pol V also has a role in bypass of *N*²-benzo[a]pyrene–dG as well as certain oxidation products of G.

Figure 4 Environmental mutagens such as (a) UV radiation and chemical mutagens like hydroxyl radicals (b), among many other agents, contribute to DNA damage. Common UV photoproducts are modified thymine bases, such as thymine–thymine 6–4 photoproducts and *cis-syn* thymine–thymine cyclobutane pyrimidine dimers (CPDs). Hydroxyl radicals, as well as other agents including ionizing radiation, can lead to the formation of abasic sites. Abasic sites are also generated spontaneously. Pol V bypasses all of the lesions shown.

Pol V has low fidelity when copying undamaged DNA, with error rates of 10^{-3} – 10^{-4} compared to pol III, which is 100–1000-fold more accurate than pol V. Y family polymerases are characterized by low processivity; pol V inserts about 6–8 nt prior to dissociation from the DNA. The processivity of pol V is increased only modestly by the β processivity clamp.

Characteristics of Y Family Polymerases

A major reason that Y family polymerases were not identified as polymerases despite years of genetic characterization is because they possess little sequence homology to DNA polymerases from other families. While many high-resolution structures of Y family DNA polymerases have been determined, there is currently no such structure of pol V. Remarkably, Y family polymerases adopt the classical DNA polymerase right hand conformation, although with some differences. The palm region contains the active site of the polymerase where the incoming nucleotide is bound and incorporated into the primer DNA strand. The fingers and thumb regions bind the template and primer DNA strands. A little finger domain unique to the Y family polymerases makes contacts with the DNA that may facilitate specific lesion bypass and processivity.

In general, replicative DNA polymerases ensure exquisite accuracy through a combination of mechanisms. They have active sites that enforce correct base pairing on the incipient base pair due to their tight fit and relatively closed

conformation. Y family polymerases have open, solvent-accessible active sites, which allow bulky lesions to be bound in the active site and are less selective when binding undamaged DNA. Replicative polymerases have an α -helix, the so-called O helix, that ensures the fidelity of the newly forming base pair. Y family polymerases are clearly missing the O helix and thus lack this important contribution to specificity. Replicative polymerases have either intrinsic or associated 3' to 5' exonuclease domains that proofread the newly formed base pair and can remove the new primer terminus if necessary. Y family polymerases lack intrinsic proofreading and thus are better able to bypass lesions without interference from proofreading, but also exhibit lower fidelity when copying undamaged DNA.

Regulation

In addition to transcriptional regulation via the SOS response and posttranslational regulation by cleavage of UmuD₂, pol V activity is regulated by interactions with a number of other proteins. Pol V is activated by RecA and requires RecA–ATP in order to sustain activity. Once pol V Mut synthesizes past the lesion and dissociates, it is no longer active and must again be activated by another RecA–ATP complex. This is a possible mechanism to limit the potentially mutagenic activity of pol V. Pol V TLS activity is stimulated by the β processivity clamp, and interactions with the β clamp are critical for UV-induced mutagenesis *in vivo*. These interactions may be important for polymerase switching or recruitment of pol V to sites of DNA damage.

Both UmuD₂ and UmuD'₂ interact with the α polymerase, β processivity, and ϵ proofreading subunits of DNA polymerase III. UmuD₂ interacts more strongly with the β clamp than UmuD'₂ does, although both interactions are detectable. It is thought that interaction of UmuD₂ with the β clamp may facilitate inhibition of replication, and that cleavage of UmuD₂ to form UmuD'₂ may release the inhibition. UmuD'₂ interacts more strongly with α than UmuD₂ does, but the significance of this interaction is currently unknown.

UmuD, UmuD', and UmuC are all regulated by proteolysis. UmuC and UmuD₂ are both substrates for the Lon protease. UmuD serves as an adaptor to deliver its partner, whether UmuD or UmuD', to the ClpXP protease for degradation. Given that the UmuDD' heterodimer is the most stable dimeric form, this may be a way for the cell to decrease the levels of UmuD', and therefore pol V, present.

Bacterial Homologs

E. coli has another member of the Y family, DinB or polymerase IV, that also copies damaged DNA but with different specificity than pol V. DinB is known to bypass N²–dG adducts, such as N²–furfuryl–dG and N²–benzo[a]pyrene–dG with high accuracy. Both UmuC and DinB are regulated by the SOS response to DNA damage. DinB, particularly at high levels, causes –1 frameshift mutagenesis, an activity that can be suppressed by UmuD₂ and RecA. The eukaryotic homolog of DinB is pol κ , and it is the only Y family DNA polymerase specifically conserved throughout all domains of life.

Homologs of *umuC* and *umuD*, found in many but not all bacteria, share significant sequence homology, similar functionality, and similar organization in operons. Homologs of UmuD tend to share the same cleavage site and to cleave in a similar manner. Examples of these are *impAB*, *samAB*, and *mucAB*. MucA and MucB are found on native conjugational plasmids. MucA cleaves itself to form MucA', much like UmuD cleavage to form UmuD'. It is said that MucA' and MucB are much stronger mutators due to the efficiency of MucA cleavage compared to UmuD. MucA' and MucB form DNA polymerase RI, which requires RecA and SSB for lesion bypass. Notably, the *mucAB* genes are found on pKM101, a plasmid added to the *Salmonella* spp. strains used in the Ames mutagenicity test.

Eukaryotic Homologs

Y family polymerases are conserved throughout all domains of life. Humans have four members of the Y family, specifically Rev1, pol ι, pol κ, and pol η. It is possible for DNA polymerases other than those in the Y family to perform TLS, with the B family polymerase pol ζ being one notable example. The yeast *Saccharomyces cerevisiae* lacks an identifiable gene for pol κ, although pol κ is present in other yeast species. Rev1 promotes mutagenesis in both organisms mentioned above, as well as others. Interestingly, the *REV1* gene is required for TLS past the (6–4) thymine–thymine UV photoproduct, even though the Rev1 polymerase cannot bypass the lesion. The catalytic activity of Rev1 is not required for all TLS events for which the protein itself is required, suggesting that Rev1 has a scaffolding role in TLS. Pol κ is the eukaryotic homolog of DinB and exhibits similar lesion specificity. Pol ι uses Hoogsteen base pairing with damaged template bases in an unusual mode of DNA synthesis.

Pol η is a functional homolog of pol V. Pol η is known to bypass T–T CPD dimers in an error-free manner. It is most well known for the consequences of loss of its activity. Humans deficient in pol η develop xeroderma pigmentosum variant (XPV), which is a genetic disorder causing skin to be extremely vulnerable to UV radiation from the sun, leading to a high incidence of skin lesions and skin cancer. The disease stems from an increase in UV mutagenesis due to other polymerases substituting for pol η in a potentially error-prone manner.

Other forms of XPVs stem from defects in nucleotide excision repair, an accurate repair pathway.

Conclusions

DNA damage is ubiquitous and multiple pathways exist to respond to such damage. The widespread conservation of Y family DNA polymerases indicates their importance for all organisms. Most Y family polymerases, especially *E. coli* pol V, are potentially mutagenic and therefore potentially harmful. Therefore, while their functions are clearly important, proper regulation is also crucial.

Uncoupling Proteins

D Ricquier and F Bouillaud, Centre National de la Recherche Scientifique and Université Paris Descartes, Paris, France

© 2013 Elsevier Inc. All rights reserved.

Glossary

Mitochondria These organelles are the sites of respiration and oxidative phosphorylation in all animal and higher plant tissues as well as in protozoa, fungi, and aerobically grown yeasts. They are ~2–30 µm long and 0.5–10 µm wide.

Mitochondrial transporters The uncoupling proteins (UCPs) actually belong to a family of membranous mitochondrial transporters including the adenosine diphosphate/adenosine triphosphate (ADP/ATP) translocator, the phosphate carrier, the oxoglutarate carrier, the citrate carrier, and the acylcarnitine carrier. All these

transporters play an important role in the metabolic dialog between cytosol and mitochondria. They all derive from the same ancestor gene.

Respiration coupling/uncoupling In coupled mitochondria, respiration rate determines ADP phosphorylation rate and ATP synthesis determines respiration rate. When uncoupling occurs (due to chemical uncouplers or UCP), the respiration rate increases sharply since the control by ADP phosphorylation does not limit respiration. In such a situation, oxidation energy is dissipated as heat.

Introduction

Uncoupling proteins (UCPs) are mitochondrial transporters present in the inner membrane of mitochondria. They belong to the family of anion mitochondrial carriers including adenine nucleotide transporters, phosphate carrier, and other transporters. The term ‘uncoupling protein’ was originally given to UCP1 which is uniquely present in mitochondria of brown adipocytes, the thermogenic cells devoted to maintenance of body temperature in mammals. In these cells, UCP1 acts as a proton carrier creating a shunt between complexes of respiratory chain and the adenosine triphosphate (ATP)-synthase. Purine nucleotide inhibits UCP1, whereas fatty acids activate it. Activation of UCP1 stimulates respiration and the uncoupling process results in a futile cycle and dissipation of oxidation energy into heat. UCP2 is ubiquitous and highly expressed in lymphoid system and macrophages and also in gut, lung, and brain. UCP3 is mainly expressed in skeletal muscles. In comparison to the established uncoupling and thermogenic activities of UCP1, UCP2, and UCP3 rather appear to be involved in the limitation of free radicals levels in cells than in physiological uncoupling and thermogenesis. These novel UCPs are also involved in sparing glucose utilization and consequently in the control of fatty acids and glutamine metabolism. The mechanism of the protonophoric activity of UCP1 is still controversial since it has been proposed that UCP1 transports fatty acid anions and catalyzes proton transport by fatty acid cycling. Quinones and superoxide ions may also activate the UCPs.

The Mitochondria and the Coupling of Respiration to ADP Phosphorylation

Cellular respiration, the reactions of the citric acid cycle, fatty acid oxidation, and several steps of urea synthesis and steroid hormone synthesis and gluconeogenesis take place in specialized cellular organelles, the mitochondria.

Mitochondria

In addition to oxidative phosphorylation and metabolic pathways, mitochondria are involved in thermogenesis, radical production, calcium homeostasis, apoptosis, and protein synthesis. Mitochondria contain two compartments bounded by inner and outer membranes. The outer membrane is permeable to many small metabolites whereas the permeability of the inner membrane is controlled in order to maintain the high electrochemical gradient created by the mitochondrial respiratory chain, which is necessary for energy conservation and ATP synthesis in mitochondria. The inner membrane transports anion substrates such as adenosine diphosphate (ADP), ATP, phosphate, oxoglutarate, citrate, glutamate, and malate.

Coupling of Respiration to ATP Synthesis

It has long been known that respiration and mitochondrial ATP synthesis are coupled. The observation that respiration rate increased when mitochondria synthesized more ATP led to the concept of respiratory control by ADP phosphorylation. In fact, there is a link between mitochondrial ATP synthesis and cellular ATP demand by a feedback mechanism. In agreement with Mitchell's theory, it was demonstrated that the mitochondrial electrochemical proton gradient, generated as electrons are passed down the respiratory chain, is the primary source for cellular ATP synthesis. In this way, several complexes of the respiratory chain pump protons outside of the inner membrane during reoxidation of coenzymes and generate a proton gradient, which is consumed by the reactions of ATP synthesis. Proton leak represents another mechanism consuming the mitochondrial proton gradient. Mitchell's theory predicted that any proton leak noncoupled to ATP synthesis would represent an uncoupling of respiration and result in thermogenesis. An excellent example of such an uncoupling of respiration to ADP phosphorylation is represented by the mitochondrial UCP of brown adipocytes (UCP1) which dissipates energy of substrate oxidation as heat.

Brown Adipose Tissue and UCP1: History of a True Respiration Uncoupling

Maintenance of body temperature in a cold environment or at birth requires thermogenesis. Another situation requiring thermogenesis is arousal from hibernation. The two regulatory thermogenic processes are shivering and metabolic thermogenesis also referred to as nonshivering thermogenesis. The largest part of nonshivering thermogenesis in small mammals is achieved in the brown adipose tissue (BAT).

Brown Adipose Tissue

BAT is easily found in all small mammals and in the newborn of larger mammals, such as humans. Recent data based on the use of positron emission tomography-SCAN analysis of glucose uptake have demonstrated that BAT is present in human adults. BAT is located in specific body areas near large blood vessels and consists of brown adipocytes which are distinct from white adipocytes. The brown adipocytes are characterized by numerous mitochondria containing a highly developed inner membrane (Figure 1). Activation of thermogenesis in BAT occurs in newborns, rodents exposed to cold, and in animals emerging from hibernation. It is commanded by the central nervous system and the orthosympathetic fibers innervating each brown adipocyte. The norepinephrine

released by these fibers binds to adrenergic receptors on the surface of the brown adipocytes. The later steps of the activation of thermogenesis in brown adipocytes are production of cyclic adenosine monophosphate, activation of lipolysis, and oxidation of fatty acids by the numerous mitochondria. Released fatty acids stimulate brown adipocyte respiration and heat production.

Respiration Uncoupling Is the Thermogenic Mechanism in Brown Adipocytes

In most cell types such as muscular fibers, ATP utilization stimulates ADP phosphorylation and respiration (Figure 2). Original observations made in 1967 revealed that the high respiratory rate in brown adipocyte mitochondria was not controlled by mitochondrial ADP phosphorylation suggesting that energy from substrate oxidation was dissipated into heat instead of being converted into ATP (Figure 2). In line with Mitchell's chemiosmotic theory, if proton leakage is activated by a signal such as free fatty acids in the case of the mitochondria of brown adipocytes, the mitochondrial membrane potential is decreased and concomitantly, respiration is activated. Since, in addition, the activated proton leakage is not linked to ADP phosphorylation, respiration is uncoupled from ATP synthesis and oxidation energy is dissipated in the form of heat.

The UCP of Brown Adipocyte Mitochondria

The protein responsible for proton leakage within the inner mitochondrial membrane and for respiratory uncoupling was identified in 1976–77, was purified, and its complementary DNA (cDNA) was cloned. It has an apparent molecular weight of 33 000 and was originally called UCP. This protein is known as UCP1 since the discovery of UCP2 in 1997. UCP1 is abundant in the inner membrane of the mitochondria of brown adipocytes and is specific to these cells. It short-circuits the proton circuit between complexes of the respiratory chain and the mitochondrial ATP-synthase, which is the main consumer of the proton gradient (Figure 3). When there is no need for thermogenesis, purine nucleotides bound to UCP1 inhibit its activity. Upon activation of thermogenesis by the sympathetic nervous system, fatty acids overcome the inhibitory effect of nucleotides and activate UCP1. Heterologous expression of UCP1 in yeasts or mammalian cell lines induces respiration uncoupling. The protonophoric activity of UCP1 has been reconstituted in liposomes where it can be inhibited by nucleotides and activated by free fatty acids. The mechanism of action of UCP1 is still controversial: some scientists believe that it is a true proton transporter, while others assert that it returns anionic fatty acids to the intermembrane space, after they have crossed the membrane in protonated form. The observation that *Ucp1^{-/-}* mice were unable to maintain body temperature in the cold proved that the UCP1-induced uncoupling of respiration was responsible for cold-activated nonshivering thermogenesis of rodents. In agreement with this observation, ectopic expression of UCP1 in skeletal muscles of transgenic mice promotes substrate oxidation in muscles and resistance to obesity and type 2 diabetes. UCP1 functions as a dimer and each monomer is made of six transmembrane

Figure 1 Histology of brown adipocyte. (a) The cytosol of brown adipocytes is characterized by numerous mitochondria and lipid droplets. Figure 2 Comparison of skeletal muscle and brown adipose tissue mitochondria. (a) Mitochondria are cellular organelles converting the redox energy liberated during oxidation of organic substrates into ATP, a molecule containing energy under a form readily usable by most enzymes working to maintain cell structure and integrity or to perform work such as mechanical work in muscle. The cellular need for ATP controls oxidation rate by mitochondria. (b) In brown adipocyte, a specific uncoupling protein referred to as UCP (precisely UCP1) is present in a large amount in the inner membrane. UCP1 is able to fool mitochondria which accelerates their oxidation rate whereas no ATP is produced. UCP1 removes the control of energy expenditure by ATP demand and therefore oxidation rate and energy expenditure increase under the form of heat. This process is used in newborns, during arousal from hibernation, and in young and adult mammals exposed to cold when muscle thermogenesis would not be sufficient.

Figure 3 UCP1-induced proton cycling. Q (coenzyme Q) refers to complex II, which is the succinate dehydrogenase. This enzyme directly reduces coenzyme Q but has no proton pumping activity contrary to complexes I, III, and IV. UCP is inserted in the mitochondrial inner membrane where a multienzymatic complex called the 'respiratory chain' made of complexes I–IV is also present. The respiratory chain reoxidizes reduced coenzymes and electrons are driven to oxygen. This oxido-reduction step liberates energy, which is used to generate an electrochemical gradient of protons across the inner membrane. This gradient is normally consumed by the ATP-synthase, which phosphorylates ADP. UCP1 transports protons passively and makes possible a futile cycle of protons across the inner membrane leading to increased energy expenditure. This schema illustrates the situation encountered in brown adipocytes of mammals where a large amount of respiratory chains as well as a large amount of UCP1 are present. Activation of the futile cycling increases considerably energy expenditure and thus heat production in these thermogenic cells. In other cells where homologs of the UCP1 are expressed at a much lower level, this pathway would represent a minor contributor to energy expenditure, but might be of importance to avoid oxidative damage.

fragments (Figure 4). Moreover, UCP1, the ADP/ATP translocator, and other mitochondrial anion carriers derive from the same ancestral gene and probably share a similar structure. They all have a triplicated structure (Figure 4).

The Novel UCPs

Given their specific role in thermogenesis, it has always seemed logical that brown adipocytes be equipped with an original mechanism, partial and regulatable uncoupling of respiration, brought into play by a specific protein, UCP1, which induces proton leakage. In fact, it is known that mitochondrial respiration is always accompanied by heat production as it is imperfectly coupled to ADP phosphorylation in all types of cells. To explain this incomplete coupling of respiration and the energy loss mechanism, some authors have invoked slippage of the respiratory chains, while others referred to proton leaks. It has been estimated that proton leaks from the inner membrane of mitochondria of hepatocytes and myocytes could explain about 20% of the body's basal metabolism.

UCP2: A Homolog of the Brown Fat UCP Present in Various Tissues

A clone corresponding to a protein with 59% sequence identity with the UCP of brown fat was isolated. This new UCP, called UCP2, was also identified in humans. In contrast with UCP1, the messenger RNA (mRNA) of UCP2 is present in almost all tissues and many cell types, such as spleen, thymus, digestive

Figure 4 Model of insertion of UCP in the membrane. To modelize the organization of such proteins, indirect methods such as prediction of secondary structure by computers can be used. Experimentally, restricted domains of the protein in the membrane (indicated by stars) were explored using specific antibodies. The UCPs are made of six transmembrane segments (probably alpha helices) and three hydrophilic loops stemming from the matricial side of the membrane. An internal repetition in the structural arrangement of the protein suggests that the protein (made of 300 amino acid residues) is derived from the ancient triplication and divergence of a 100-amino-acid domain (made of two helices and one loop). This model fits with the structure of the mitochondrial ADP-ATP carrier recently identified by crystallization and X-ray diffraction analysis by Pebay-Peroula and Brandolin teams.

Figure 5 Tissue distribution of UCP1, UCP2, and UCP3 RNAs. The data correspond to mouse tissues. A very similar picture was obtained when analyzing human tissues. 18S refers to ribosomal RNA.

tract, lung, brain, adipose tissues, skeletal muscle, heart, adipocytes, myocytes, and macrophages (Figure 5). Expressed in yeasts, murine UCP2 decreased the potential of the mitochondrial membrane, raised the respiration rate, and reduced sensitivity to uncouplers: UCP2 therefore was able to uncouple respiration and appeared to be a second mitochondrial UCP. However, recent data do not support the idea that this uncoupling activity of UCP2 takes place *in vivo* and other transport activities might well be more relevant to physiology. The UCP2 gene is located on chromosome 7 of the mouse and chromosome 11 of humans, near a region linked to hyperinsulinism and obesity. The expression of UCP2 mRNA was measured in

obesity-prone and obesity-resistant mice given a lipid-rich diet: the obesity-resistant mice overexpressed UCP2 mRNA in their adipose tissue. These findings, together with the function of the protein and the chromosomal location of its gene, led to propose a role for UCP2 in diet-induced thermogenesis. However, this hypothesis was not validated in *Ucp2*^{-/-} mice.

UCP3: Another UCP Homolog Predominantly Present in Skeletal Muscle

cDNAs corresponding to UCP3, a protein homologous to UCP1 and UCP2, were cloned soon after the discovery of UCP2. The amino acid sequence of UCP3 is 72% identical to that of UCP2 and 57% identical to that of UCP1. UCP3 mRNA is predominantly expressed in the skeletal muscles of humans, mice, and rats (Figure 5). Human and murine UCP2 and UCP3 genes are juxtaposed on the same chromosome.

Plant and Bird UCPs

Functional studies of isolated plant mitochondria suggested that plants contain mitochondrial UCPs. Following this observation, a cDNA from a new UCP was isolated from a potato cDNA library. The sequence of the corresponding protein, called 'stUCP', is 44% identical to that of UCP1 and 47% identical to that of UCP2. The mRNA of stUCP is present in most plant organs. The most surprising result was that stUCP mRNA was markedly induced in the leaves of plants exposed to a temperature of 4 °C. Cold, therefore, induced stUCP as it induces UCP1 in the BAT of animals. However, plant and animal UCPs may have different functions. More recently, a chicken UCP termed 'avUCP' was characterized. This gene is only expressed in skeletal muscles of birds and ducks and is induced upon exposure to the cold. Therefore, avUCP seems to be involved in regulatory thermogenesis. Other proteins referred to as UCP4 and BMCP1/UCP5 were characterized. However, their exact relationship to UCP1, UCP2, and UCP3 will require further work.

Role and Function of UCPs other than UCP1: A Role in Controlling the Level of Reactive Oxygen Species and a Role in Glucose Metabolism

Reactive oxygen species

Guided by the fact that UCP2 is expressed at high level in the immune system, a role for UCP2 in immunity was searched for. In fact, *Ucp2*^{-/-} mice are more resistant to infection by a parasite. This phenotype was explained by the fact that disruption of the *Ucp2* gene provoked an elevation of reactive oxygen species (ROS) level that facilitated the killing of the pathogens. Mice lacking the *Ucp3* gene also produced more oxygen radicals in myocytes. Therefore, it appears that UCP2 and UCP3 contribute to limit the level of ROS in cells. Such an activity may be explained by a mild uncoupling activity of the proteins since a small decrease of the mitochondrial membrane potential opposes production of superoxide ion in mitochondria (Figure 6). The observation that UCP2 protects against atherosclerosis highlights its ability to counteract radical synthesis.

Numerous questions remain unanswered, notably concerning the exact catalytic activity of each UCP, and the nature

Figure 6 Role of UCP and superoxide generation by mitochondria. (a) Mitochondria phosphorylating ATP: a proton gradient generator (the respiratory chain, left square) uses the energy liberated by the movement of electrons to pump protons through the membrane (gray zone) towards the intermembrane space. A proton gradient consumer (the ATP-synthase, right square) phosphorylates ADP coming from outside into ATP, that is exported afterwards. Therefore, a proton cycle across the inner membrane couples oxidation to ATP synthesis (and *vice versa*). (b, c) When oxidation is impaired (b) or slows down (c), an excess of electrons aiming to travel across the respiratory complexes cannot reach oxygen (to form water). Single electrons react with molecular oxygen and form superoxide anion ($O_2^{\bullet-}$). It occurs either when the respiratory chain is poisoned (red arrow in panel b) or under physiological circumstances when the use of ATP by the cell is weak, ATP level rises, and ADP level decreases (panel c). In that case, the membrane potential rises to its highest value which impedes proton pumping, slows down reoxidation, and therefore increases superoxide production. (d) In tissues other than the thermogenic brown adipose tissue, the UCPs may induce a controlled leak of protons across the inner membrane that allows reoxidation to occur and maintain the membrane potential below the threshold inducing superoxide generation. The mechanism of proton transport (proton channeling or fatty acid cycling), as well as the identity of regulators of UCPs inside the cells are still controversial. Fatty acids would be

of the endogenous ligands of UCP2 and UCP3. These proteins may simply translocate protons. As said above for UCP1, it has been proposed that all the UCPs are active as fatty acid cyclers through the membrane. According to this later hypothesis, protonated fatty acids cross the membrane and release a proton on the matricial side; then, the UCP facilitates the translocation of the anionic form of fatty acids. High loads of UCP2 or UCP3 can uncouple respiration in yeast or mammalian cell, but it is not certain whether the low physiological levels of these proteins may be sufficient to induce a net uncoupling of respiration *in vivo*. The divergent observations of the regulation of the activities of UCP2 or UCP3 by fatty acids or nucleotides will require further studies. Interestingly, it has been proposed that UCP2 and UCP3 could export fatty acid anion under conditions of elevated fatty acid oxidation.

Metabolic activity of UCP2 and UCP3

Conflicting data regarding the association of UCP2 or UCP3 genetic polymorphisms to body mass index, susceptibility to obesity, resting metabolic rate, metabolic efficiency, fat oxidation, insulin resistance, and susceptibility to gain fat with age were obtained. However, UCP2 appears to act as a negative regulator of insulin secretion. Moreover, mice overexpressing a large amount of human UCP3 in skeletal muscle weigh less, have a decreased amount of adipose tissue, and an increased resting oxygen consumption. Recent data suggest that UCP2 and UCP3 favor glucose sparing and oxidation of alternate substrates (glutamine and fatty acids) in cells; this would be explained rather by the transport of a metabolite (pyruvate?) out of mitochondria than by uncoupling.

UCP1, UCP2, and UCP3, Conclusions and Perspectives

UCP1 has a well-demonstrated uncoupling activity and an essential role in maintenance of body temperature in small rodents exposed to the cold, but the exact biochemical and physiological roles of UCP2 and UCP3 remain to be further identified. Certain data support a true activity of these UCPs in respiration uncoupling and substrate oxidation, other data do not agree with a role for these UCPs in controlling adiposity. Several reports support a role for UCP2 and UCP3 in decreasing the level of ROS in cells. While UCP1 is present at a high level, an open question is that of the exact amount of UCP2 and UCP3 in cells since whatever is the exact intrinsic ability of these proteins to uncouple respiration from ATP synthesis, a certain amount of the proteins will be required to achieve a physiological uncoupling. Finally, the possible contribution of a UCP to the hypermetabolic syndrome (known as Luft's disease) previously described in patients remains to be investigated.

cofactors of the proton transport whereas nucleotides are inhibitors. The membrane potential itself is a variable influencing heavily UCP1 activity. It has been proposed that superoxide anion and quinones directly activate proton transport by UCPs.

Glossary

Chaperone A protein that assists folding and assembly of other proteins and prevents their aggregation in the unfolded state.

Endoplasmic reticulum A membrane-bound organelle, present in all nucleated cells, which serves as the entry point for secreted proteins.

Proteotoxicity A hypothetical property of unfolded and misfolded proteins, whereby peptide domains that are illegitimately exposed on the surface perturb cellular function.

The unfolded protein response (UPR) is a transcriptional and translational response to the accumulation of unfolded proteins in the endoplasmic reticulum (ER). The UPR is mediated by highly conserved signaling pathways that are activated by imbalance between the load of unfolded (or misfolded) ER client proteins and the capacity of the organelle to process this load. Collectively, these pathways restore equilibrium to the protein-folding environment in the organelle by increasing the expression of genes that enhance nearly all aspects of ER function and by transiently repressing the biosynthesis of new client proteins. Interest in the UPR has been stimulated by the realization that postsynthetic protein-processing constitutes an important step in gene expression and that protein misfolding plays an important role in human disease.

ER Function and ER Stress

The ER: A Protein-Processing Machine

Proteins destined for secretion and membrane insertion are translocated across the ER membrane in an unfolded state. In the ER lumen, they undergo chaperone-assisted folding, a variety of organelle-specific posttranslational covalent modifications and often chaperone-assisted assembly into oligomeric structures. Once properly folded and assembled, most ER client proteins are packaged into vesicles that are transported to more distal sites in the secretory pathway. Proteins that fail to attain their proper folded and oligomeric conformation are retained in the ER by continued binding to chaperones and are ultimately translocated from the organelle to the cytoplasm for proteasomal degradation, in a process known as ER-associated protein degradation.

To fulfill these various functions, the ER is endowed with a unique complement of proteins. These include enzymes for posttranslational covalent modifications (e.g., N-linked glycosylation and disulfide bond formation), chaperones that assist in folding and assembly steps, translocation channels and transporters involved in transmembrane traffic, and various components involved in the postassembly steps of client protein egress from the organelle. The buildup of these components defines the capacity of the organelle to handle its client proteins. In the late 1980s, Sambrook, Gething, and

their colleagues discovered that manipulations that interfere with the function of various aspects of the ER client protein-handling machinery, and thereby perturb protein folding in the ER, selectively upregulate the expression of genes that encode components of that machinery. The extent of this transcriptional response was not fully appreciated at the time; however, its selectivity was noted, hence its name: the ER UPR.

It was imagined that the cell possessed means to monitor the load of client proteins presented to its ER and responded to an increase in such load by upregulating the capacity of its ER to process unfolded client proteins. An additional clue to the workings of this response was provided by the seminal observation that forced overexpression of an ER chaperone, BiP (also known as GRP78) markedly suppressed the activity of the UPR. Thus, at least one target gene of the UPR (BiP) is able to exert negative feedback on the entire response. BiP overexpression does not restore function to a challenged ER; this requires the coordinate expression of numerous UPR target genes. However, BiP, which is a member of the highly conserved HSP70/DnaJ family of chaperones, promiscuously recognizes hydrophobic stretches of amino acids. These are normally incorporated into the cores of properly folded polypeptides and assembled oligomeric complexes, but remain exposed on the surface of unfolded, misfolded, or unassembled proteins. The ability of BiP to suppress the UPR suggested that it might be doing so by masking a stress signal generated by many different unfolded and misfolded proteins. This phenomenon was assigned the heuristic term ER stress and its level reflects the balance between client protein load and the capacity of the organelle to process that load.

Physiological and Pathological ER Stress

To the extent that cell types vary in the load of secreted proteins that they are called upon to produce, they are subject to widely different levels of physiological ER stress. This explains enhanced activity of the UPR in various professional secretory cells, such as pancreatic cells of vertebrates or intestinal cells of the nematode, *Caenorhabditis elegans*. ER stress also occurs when a mutation in an abundantly expressed ER client protein renders that protein especially difficult to fold. An example is

provided by various degenerative diseases affecting myelinated neurons in which mutations in a component of the myelin sheath (an ER client protein) cause the protein to misfold and induce high levels of ER stress which, over time, destroys the myelin-producing cell. It is important to emphasize that most mutations that impede folding of ER client proteins do not cause measurable ER stress. However, because they diminish expression of the properly folded protein, such mutations may deprive the organism of the latter's beneficial actions. This genetic mechanism underlies such serious human diseases as cystic fibrosis, familial hypercholesterolemia, and hemophilia. Nonetheless, the level of expression of the mutant protein is not enough to globally challenge ER function in the cell that produces it and the phenotypic expression of the mutation reflects the lack of an important protein, rather than the production of a toxic one.

The above constitute client protein-driven ER stress; however, ER stress may also initiate from impaired function of the organelle, which occurs in cells deprived of energy sources or oxygen, or in cells exposed to certain ER-specific toxins. We do not understand, in detail, how ER stress contributes to further organelle dysfunction and ultimately cell death. However, a framework for thinking about this has recently emerged with the realization that unfolded and misfolded proteins may disrupt the cellular machinery by interacting promiscuously and illegitimately with essential cellular components. According to this theory, proteotoxicity is normally held in check by the chaperones that bind such potentially toxic protein interfaces and let go only once the latter have been buried in the hydrophobic cores of the properly folded client protein. ER stress (by definition) challenges the capacity of the chaperones and may permit illegitimate protein interfaces to emerge. The ability of chaperone overexpression to suppress ER stress signaling suggests that the need to prevent proteotoxicity is an important driving force in evolution of the UPR. The unifying feature of ER stress need not be the presence of toxic moieties on the surface of every unfolded or misfolded protein. The common feature of diseases of protein folding might instead be the exhaustion of a protective chaperone reserve, which normally suppresses the potential proteotoxicity of certain (possibly normal) folding intermediates of ER client proteins.

The Yeast UPR

Inositol Requiring 1: A Prototype of Transmembrane Stress Signaling

Early studies on the UPR were carried out in the yeast, *Saccharomyces cerevisiae*, an organism that lends itself well to forward genetic screens. To screen for mutations affecting the UPR, the regulatory region of yeast BiP gene (KAR2) was fused to a reporter and mutant yeast with suppressed activity of this reporter was sought. The first gene, thus, identified was inositol requiring 1 (IRE1), so-called because its loss of function had been previously noted to result in inositol auxotrophy. IRE1 encodes a transmembrane ER-resident protein with an N-terminal domain residing in the ER lumen and a C-terminal domain that is exposed on the cytoplasmic side.

The membrane topology and subcellular localization of IRE1 immediately suggest a mechanism for transmitting information on the state of the ER (topologically equivalent to the extracellular space) to the cell's interior. The luminal domain somehow senses ER stress, conveying the signal across the ER membrane to the cytoplasmic domain, which broadcasts it to the nucleus, turning 'on' UPR target gene expression (Figure 1).

IRE1's C-terminal, cytoplasmic, effector domain, is a protein kinase and undergoes autophosphorylation when activated by ER stress. This suggested that IRE1 might function like other transmembrane receptors that are also protein kinases and convey their signal by phosphorylating downstream targets, often through a kinase relay. However, other than IRE1 itself no substrates for the aforementioned kinase have been identified to date.

Unconventional Splicing of HAC1 Messenger RNA

The clues to understanding propagation of the UPR signal, downstream of IRE1 again came from yeast genetics. Mutations in two additional genes were noted to block the yeast UPR. One of these, HAC1, encodes a transcription factor, which binds to and activates the promoters of the primary target genes of the yeast UPR, the second, more mysteriously turned out to be RLG1, which encodes a multifunctional enzyme involved in transfer RNA (tRNA) splicing. ER stress promotes accumulation of HAC1 protein and this is blocked by mutations in IRE1 and RLG1. The underlying mechanisms, which turned out to be full of surprise, were revealed in a series of brilliant experiments carried out in the Walter and Mori laboratories.

The regulated step in HAC1 expression entails the removal of a 242-base internal segment at the 3' end of the mature messenger RNA (mRNA). The enzyme which precisely cuts the mRNA at the 5' and 3' ends of this segment turned out to be IRE1 itself, whose highly sequence-specific endoribonucleolytic activity is subordinate to its kinase activity by phosphorylation-dependent nucleotide binding and dimerization of IRE1's composite kinase and RNase domain. The two ends of the severed HAC1 mRNA are held together by extensive base pairing and are subsequently religated by the protein product of RLG1. IRE1 is the master regulator of this unconventional mRNA-splicing reaction, because its kinase and endoribonuclease are activated by ER stress. The removal of the aforementioned internal segment of the HAC1 mRNA derepresses HAC1 translation and the protein encoded by the processed mRNA is more stable and transactivates its target genes more potently than that encoded by the unprocessed mRNA.

Mutations in IRE1 and HAC1 similarly abolish most signaling in the yeast UPR. This was convincingly demonstrated by expression profiling which showed that the vast majority of the genes induced by exposing yeast to toxins that promote ER stress were no longer activated in IRE1 or HAC1 mutant strains. Thus, the yeast UPR consists of a linear pathway in which HAC1 is an essential target of IRE1 and together the two proteins are required for the activation of most known UPR target genes.

Figure 1 IRE1 and unconventional splicing of its target mRNA signal the unfolded protein response. ER stress leads to oligomerization and *trans*-autophosphorylation of IRE1 (indicated by the 'P' on its cytoplasmic effector domain). Phosphorylation unmasks the effector function of IRE1 (cartooned by the red bristles on the cytoplasmic domain), which consists of the endoribonucleolytic processing of its target mRNA, XBP-1 in metazoans, and HAC1 in yeast. The two ends of the cleaved mRNA are joined together by a ligase. The unconventionally spliced XBP-1/HAC1 mRNA is more efficiently translated than the unprocessed mRNA and encodes a protein that is more stable and more effective at *trans*-activation of UPR target genes in the nucleus.

Diversification in the Metazoan UPR

Conservation of the IRE1 Pathway

IRE1 is conserved in all eukaryotes as is its ability to cleave a unique substrate RNA. The counterpart of HAC1 in metazoans is the XBP1 mRNA whose unconventional splicing mechanism is conserved in many (though not all) details between yeast and mammals. Less conserved, however, is the role of the IRE1 pathway in the yeast and metazoan UPR. Whereas in the former, IRE1 and HAC1 are absolutely required for activating nearly all UPR target genes; in mammals, IRE1 and XBP-1 are dispensable for activation of all but a very small set of UPR targets. This is all the more remarkable when one considers that most UPR target genes are conserved between yeast and mammals, it is just that the latter have found alternative means to couple their expression to ER stress. *C. elegans* occupies an intermediate position between yeast and mammals, in that most of its identifiable UPR targets are partially dependent on IRE1 and XBP-1, but can, to some extent, also be activated independently of that pathway.

Despite this redundancy in the mammalian UPR, both IRE1 and XBP-1 are essential for embryonic development (mammals have two IRE1 genes, a nonessential beta isoform restricted in its expression to the intestinal and bronchial epithelium and a broadly expressed alpha isoform which is essential). The reason(s) for the embryonic lethality of IRE1 α and XBP-1-null animals are not fully understood, but it is hypothesized that in mammals the pathway may have diverted to specify the capacity for especially high levels of protein

secretion. This hypothesis, which is clearly in need of further experimental support, suggests that specification of a secretory cell fate activates a conserved stress pathway that drives a developmental process, namely acquisition of an apparatus required by professional secretory cells for high-capacity protein secretion. This idea is further supported by the observation that many UPR target genes function far downstream in the secretory pathway rendering it unlikely that such genes merely relieve the stressed ER of its load of unfolded client proteins.

ATF6 and Intramembrane Proteolysis in the Metazoan UPR

The identification of ATF6 by Mori and colleagues confirmed the predicted redundancy in the metazoan UPR. Like IRE1, ATF6 is also an ER-localized transmembrane protein. However, its cytoplasmic effector domain consists of a transcription factor that activates UPR target genes directly. In its membrane-bound form, ATF6 is inert, as it cannot reach the nucleus. Activation involves regulated intramembrane proteolysis, which liberates the transcription factor part of ATF6 from the ER membrane under conditions of ER stress (Figure 2). The next surprise came when Brown, Goldstein, Prywes, and colleagues identified the proteases involved in this highly regulated event. These turned out to be the same proteases that process and activate the membrane-bound transcription factor, SREBP, which regulates genes involved in sterol and fatty acid biosynthesis and assimilation.

There are two ATF6 genes in mammals and knockout of both isoforms is lethal. Furthermore, cells compromised in

Figure 2 ATF6 activation by regulated intramembrane proteolysis. Membrane tethering inactivates the transcription factor ATF6, whose effector domain is prevented from accessing its target genes in the nucleus. BiP binding to the luminal domain of ATF6 retains the protein in the ER compartment. However, under conditions of ER stress, BiP dissociates from ATF6, which then migrates (presumably by vesicular transport) to a post-ER compartment that contains the proteases that liberate the effector domain to signal in the UPR.

ATF6 function have important defects in UPR target gene expression. It seems likely, therefore, that mammalian ATF6 has picked up some of the role performed by IRE1 and XBP-1/HAC1 in simpler organisms. The similarities between ATF6 and the SREBPs highlight another remarkable feature of the UPR. IRE1 and HAC1 mutant yeast are unable to synthesize adequate amounts of the membrane phospholipid precursor, inositol. Although the details remain to be worked out, insufficiency of membrane lipid components also signals through the yeast UPR and enzymes involved in phospholipid metabolism are targets of IRE1 and HAC1. In metazoans, this aspect of the UPR apparently has been split off and relegated to dedicated transcription factors, the SREBPs that are activated by insufficiency of lipid components. However, the ancient link between the client protein-based UPR and membrane lipid insufficiency signaling has remained in the form of shared machinery for proteolytic activation of ATF6 and SREBP.

Translational Control in the UPR

PERK Couples ER Stress to eIF2 α Phosphorylation and Translational Repression

In addition to activated gene expression, ER stress results in a reduction in protein synthesis. Translational repression is an active process limiting the influx of client proteins into the stressed ER and, thus, serves as a counterpart to the gene-expression program, which increases the organelle's capacity to process client proteins. Brostrom and colleagues and Kaufman and colleagues noted, early on, that translational repression by ER stress is associated with phosphorylation of the α -subunit of translation initiation factor 2 (eIF2 α) on serine 51. This phosphorylation site is conserved in all eukaryotes and serves to regulate translation initiation in diverse stressful conditions. Trimeric eIF2, in complex with guanosine

triphosphate (GTP), recruits the amino-acylated initiator methionyl-tRNA to the small ribosomal subunit, allowing translation initiation. Recognition of an AUG initiation codon on the mRNA leads to hydrolysis of GTP to guanosine diphosphate (GDP) and dissociation of the ribosome-eIF2 complex. To participate in another round of translation initiation, the GDP bound to eIF2 must be exchanged to GTP. The enzyme catalyzing this exchange reaction (eIF2B) is inhibited by phosphorylated eIF2.

Distinct eIF2 α kinases were known to be activated by distinct stress signals; PKR by double-stranded RNA in viral infection and GCN2 by uncharged tRNAs in amino acid starvation. Our group noted the existence of a predicted transmembrane protein in the *C. elegans* genome, with an N-terminal 'extracellular' domain similar to IRE1 and an intracellular domain similar to PKR and GCN2, known eIF2 α kinases. This protein, which is conserved in metazoans (and absent from yeast) and to which we gave the name PERK (PKR-like ER Kinase), couples ER stress to eIF2 α phosphorylation and is essential to translational regulation by ER stress. Cells lacking PERK are hypersensitive to ER stress and in mammals, PERK activity is especially important for preservation of cells engaged in high levels of secretion. Thus, humans with PERK mutations and mice lacking the gene, develop diabetes mellitus and skeletal defects attributed to dysfunction of insulin- and collagen-secreting cells in the endocrine pancreas and bone, respectively.

Gene Expression, eIF2 α Phosphorylation and Integration of Signals in the UPR, and Other Stress Pathways

In addition to limiting the load of client protein on the stressed ER (by inhibiting translation of most mRNA), eIF2 α phosphorylation paradoxically activates the translation of the mRNA encoding the transcription factor ATF4 (and likely that of other regulatory proteins that remain to be discovered,

Figure 3 The eIF2 α phosphorylation-dependent integrated stress response. ER stress and other stresses activate eIF2 α kinases. Phosphorylated eIF2 inhibits translation initiation, alleviating ER client protein load, while at the same time activating the transcription factor ATF4 (and other, yet to be identified effectors). These activate a gene-expression program with several components: the eIF2 α phosphatase GADD34 promotes translational recovery and resumed client protein synthesis. Genes involved in antioxidant responses and amino acid import and assimilation promote cell survival and client protein synthesis. PERK signaling also functions synergistically with other arms of the UPR (e.g., by transcriptional activation of the IRE1 target gene XBP-1) to enhance ER client protein processing.

Figure 3). PERK, thus, plays an important role in upregulating target gene expression in the UPR. Expression profiling of ER-stressed wild-type and PERK $^{-/-}$ cells reveals a broad role for PERK in UPR-target gene expression, with mild impairment in most target genes and severe impairment in a smaller group. Among the UPR target genes that are strongly impaired in PERK $^{-/-}$ cells are genes involved in amino acid transport and metabolism and a gene, *GADD34*, which encodes a phosphatase that dephosphorylates eIF2 α and terminates signaling by PERK. The aforementioned strong PERK target genes play an important role in maintaining translation, by providing building blocks for secreted protein synthesis and by promoting eIF2 α dephosphorylation. Thus, PERK and eIF2 α phosphorylation appear to have a dual role in the UPR. Early in the response they protect the stressed cells from ER overload, whereas later they promote conditions required for synthesis of secreted proteins.

A considerable overlap exists between genes activated by ER stress and genes activated by other stressful conditions that promote eIF2 α phosphorylation. Thus, eIF2 α phosphorylation integrates signaling in several stress pathways. The extent of this integrated stress response is not fully known, but it appears to control important aspects of cellular and organismal metabolism.

A Common Mechanism for Sensing ER Stress

The identification of three different stress sensors in the UPR has allowed a comparison between their mode of activation. As mentioned earlier, overexpression of BiP and other ER

chaperones had been noted to repress signaling in the UPR. In the equilibrated ER, all three stress transducers, IRE1, ATF6, and PERK, are found in a simple complex with BiP, which binds on the luminal side to their stress-sensing domains. These complexes are rapidly dissociated under conditions of ER stress. Furthermore, dissociation precedes activation of the stress transducers. BiP dissociation promotes oligomerization of IRE1 and PERK, which, in turn, leads to *trans*-autophosphorylation and activation of downstream signaling. The crystal structure of yeast and human IRE1 luminal domain supports the prominence of dimerization in its activation and also suggest the possibility that direct binding of unfolded proteins may contribute to the stability of the dimer.

The chain of events in the case of ATF6 activation is more complex, but conceptually similar. BiP binding retains ATF6 in the ER, segregated from the proteases that release its transcription factor portion, as these are localized to a post-ER compartment. BiP dissociation liberates ATF6 to migrate to the protease-containing compartment, a migration that presumably takes place by vesicular transport. Thus, dispensable molecules of BiP, which are not engaged in chaperoning ER client proteins actively repress signaling by all three known transducers of the UPR. It would, thus, appear that the recognition of unfolded and misfolded proteins is relegated to professional chaperones and the stress transducers passively monitor the degree to which the latter are engaged by their clients. This arrangement of the upstream steps of the UPR mirrors that of the cytoplasmic heat shock response, in which unfolded proteins in the cytoplasm activate genes implicated in folding and degrading cytoplasmic proteins.

© 2013 Elsevier Inc. All rights reserved.

Glossary

Hyperammonemia The accumulation of ammonia in the blood to an untoward concentration; the result of a congenital deficiency of a constituent enzyme of the urea cycle.

Urea The major end product of the breakdown of proteins and amino acids.

Urea cycle The sequence of reactions by which the liver forms urea from ammonia.

Urea cycle defects Inherited deficiencies of one of the enzymes of the urea cycle.

The breakdown of proteins and other nitrogen-containing molecules results in the production of free ammonia. High ammonia concentrations are toxic to the brain. The primary function of the urea cycle (Figure 1) is to detoxify ammonia by converting it to urea. The urea cycle includes five enzymes: (1) carbamyl phosphate synthetase (CPS); (2) ornithine transcarbamylase (OTC); (3) argininosuccinate synthetase (AS); (4) 4-argininosuccinate lyase (AL); and (5) arginase. In addition to these constitutive enzymes, *N*-acetylglutamate synthetase is needed to produce *N*-acetylglutamate, an obligatory effector of the CPS enzyme. With the exception of OTC deficiency, which is X-linked, all have an autosomal recessive mode of inheritance.

Although individual deficiencies of these enzymes are rare, the overall prevalence of urea cycle disorders is about 1/30 000 live births. AS, AL, and arginase enzyme deficiencies can be detected using tandem mass spectrometry in newborn screening. Recently, some newborn screening programs have included OTC deficiency in their screening panel, using the glutamine/citrulline ratio as a marker of disease.

Inborn Errors of Metabolism Causing Hyperammonemia

Urea cycle disorders are the most common cause of hyperammonemia, but other inborn errors of metabolism, especially organic acidemias, can cause a comparable derangement (Table 1); the pathogenesis for hyperammonemia in some of these conditions is not fully understood.

Clinical Manifestations of Hyperammonemia

Most neonates present in a characteristic manner, regardless of genetic etiology. The affected infant is normal at birth but presents with a sepsis-like picture by 24–48 h of life. The baby ceases feeding, begins vomiting, and displays lethargy that quickly progresses to coma. Physical examination may reveal hepatomegaly, in addition to the neurologic signs of coma. Severe cases manifest increased intracranial pressure with a bulging fontanel and dilated pupils. Seizures are common.

Infants and older children with acute hyperammonemia may present with vomiting and neurologic abnormalities such as ataxia, mental confusion, agitation, irritability, and

combativeness. These manifestations usually occur during a high-protein intake or catabolic stress such as infections.

Routine laboratory tests are often normal. The blood urea tends to be very low. Hyperammonemia may stimulate the brain-stem respiratory center, leading to respiratory alkalosis. There may be mild increases in serum transaminases (alanine transaminase (ALT) and aspartate aminotransferase (AST)), since ammonia can cause swelling of hepatic mitochondria. In infants with organic acidemias, hyperammonemia is commonly associated with high anion gap acidosis and ketonuria. Newborn infants with hyperammonemia are often misdiagnosed as having sepsis and they may die without a correct diagnosis. Brain ultrasound or computed tomography (CT) imaging may reveal edema. There are no specific autopsy findings that would allow the diagnosis of urea cycle disorder or organic acidemias. It is imperative to measure plasma ammonia, amino acids, acylcarnitine levels, and urine organic acid levels in any ill infant whose clinical manifestations cannot be explained by sepsis.

Diagnosis

Hyperammonemia is common to all disorders of the urea cycle. Unfortunately, the measurement of ammonia can be difficult with false elevations noted frequently. Blood should be obtained from a free-flowing source (usually a vein) and rapidly chilled to avoid artificial production from blood cells. Each clinical laboratory should establish its own normal values for blood ammonia; some variation is common. In children and adults, the plasma ammonia concentration is usually less than 35 $\mu\text{mol l}^{-1}$. Blood concentrations in healthy newborn infants often can be as high as 100 $\mu\text{mol l}^{-1}$ in a full-term baby and 150 $\mu\text{mol l}^{-1}$ in a premature infant. The plasma ammonia concentration in the ill infant is usually more than 200 $\mu\text{mol l}^{-1}$.

An approach to the differential diagnosis of hyperammonemia in the newborn infant is illustrated in Figure 2. The age of onset of symptoms and the presence or absence of acidosis help physicians to arrive at a diagnosis of hyperammonemia. Plasma amino acids reveal abnormalities that may help the diagnosis of different urea cycle disorders. In patients with deficiencies of CPS, OTC, or *N*-acetylglutamate (NAG) synthetase, frequent findings are elevations in plasma glutamine and alanine with concurrent decrements in citrulline and arginine.

Figure 1 The urea cycle. Reactions occurring in the mitochondria are depicted in purple. Reactions shown with interrupted arrows are the alternate pathways for the disposal of ammonia. Enzymes: (1) carbamyl phosphate synthetase (CPS), (2) ornithine transcarbamylase (OTC), (3) argininosuccinic acid synthetase (AS), (4) argininosuccinic acid lyase (AL), (5) arginase, (6) ornithine 5-aminotransferase, and (7) *N*-acetylglutamate (NAG) synthetase. * HHH syndrome, hyperammonemia–hyperornithinemia–homocitrullinemia.

Table 1 Inborn errors of metabolism causing hyperammonemia

Urea cycle disorders

- *N*-Acetylglutamate synthetase
- Carbamyl phosphate synthetase (CPS)
- Ornithine transcarbamylase (OTC)
- Argininosuccinate synthetase (AS)
- Argininosuccinate lyase (AL)
- Arginase

Organic acidemias

- Propionic acidemia
- Methylmalonic acidemia
- Multiple carboxylase deficiency
- 3-Hydroxy-3-methylglutaric aciduria

Fatty acid oxidation defects

- Medium-chain acyl-CoA dehydrogenase deficiency
- Multiple acyl-CoA dehydrogenase deficiency

Other inborn errors of metabolism

- Lysinuric protein intolerance
- Hyperammonemia–hyperornithinemia–homocitrullinemia (HHH) syndrome
- Pyruvate carboxylase deficiency
- Congenital hyperinsulinism with hyperammonemia
- Transient hyperammonemia of the newborn

These disorders cannot be differentiated from one another on the basis of the plasma amino acid levels alone. A marked increase in urinary orotic acid in patients with OTC deficiency differentiates this defect from CPS deficiency. Differentiation between mutations in CPS versus NAG synthetase may require an assay of the respective enzymes. Clinical improvement occurring after oral administration of carbamylglutamate, however, may suggest NAG synthetase deficiency. Patients with deficiencies of AS, AL, or arginase have marked increases in the plasma levels of citrulline, argininosuccinic acid, or arginine, respectively. Indeed, the combination of hyperammonemia and marked hypercitrullinemia or argininosuccinic acidemia is virtually pathognomonic for these disorders. Elevated plasma levels of arginine point to the diagnosis of arginase deficiency.

Management of Acute Hyperammonemia

Patients with hyperammonemia should be treated promptly and vigorously. The severity of neurologic sequelae is dependent on the duration of hyperammonemia. Serious neurologic damage is very likely in infants with severe elevations in blood ammonia ($>300 \mu\text{mol l}^{-1}$) for more than 12 h.

Treatment lowers the blood ammonia level in two ways: (1) removal of ammonia N in a form other than urea and

Figure 2 Clinical approach to a newborn infant with symptomatic hyperammonemia.

(2) minimizing tissue protein catabolism (and, hence, ammonia production) by providing adequate calories and essential amino acids. Initially, fluids, electrolytes, glucose (10–20%), and lipids ($1\text{--}3\text{ g kg}^{-1}\text{ 24 h}^{-1}$) should be infused intravenously together. Once it is clear that blood ammonia is declining, it may be possible to add minimal amounts of protein ($0.25\text{ g kg}^{-1}\text{ d}^{-1}$), preferably as essential amino acids, to the infusate. As soon as the clinical condition of the patient allows, oral or gastric feeding with a low-protein formula ($0.5\text{--}1.0\text{ g kg}^{-1}\text{ 24 h}^{-1}$) should be started. It is essential to restrict dietary protein to the amount tolerated without causing hyperammonemia. Some authorities recommend a special diet that provides 50% of prescribed protein as essential amino acids.

Compounds such as sodium benzoate and phenylacetate lower blood ammonia by forming complexes with glycine and glutamine, respectively. The resulting conjugates are quickly excreted into urine, thereby eliminating waste N. Benzoate reacts with glycine to yield hippurate and phenylacetate conjugates with glutamine to produce phenylacetylglutamine (Figure 1). Thus, administration of phenylacetate leads to removal of 2 mol of ammonia N. Benzoate and phenylacetate now are available for both oral and intravenous use.

Arginine is a nonessential amino acid in healthy individuals, who form it in the urea cycle, but it is essential in most patients with urea cycle disorders (except arginase deficiency), in whom supplementation supplies the urea cycle with ornithine and NAG (see Figure 1). In patients with citrullinemia, 1 mol of arginine (as ornithine) reacts with 1 mol of ammonia (as carbamyl phosphate) to form citrulline. In patients with argininosuccinic acidemia, 2 mol of ammonia (as carbamyl phosphate and aspartate) react with citrulline to form argininosuccinic acid.

Citrulline and argininosuccinic acid are far less toxic and more readily excreted by the kidneys than is ammonia. Patients with OTC deficiency benefit from supplementation with citrulline ($150\text{--}200\text{ mg kg}^{-1}\text{ 24 h}^{-1}$) because 1 mol of citrulline reacts with 1 mol of ammonia (as aspartic acid) to form arginine. Administration of arginine or citrulline is contraindicated in patients with arginase deficiency. Arginase deficiency is a rare condition in which acute hyperammonemia rarely occurs as a presenting sign. In patients whose hyperammonemia is secondary to organic acidemias, treatment with arginine is not indicated because no beneficial effect from such therapy can be expected. In a newborn infant with hyperammonemia, arginine should be used until the diagnosis of urea cycle disorders is established.

Sodium benzoate, sodium phenylacetate, and arginine can be administered together for maximal therapeutic effect. A priming dose of these compounds is followed by continuous infusion until recovery from the acute hyperammonemic crisis (see Table 2). Both benzoate and phenylacetate are usually supplied as concentrated solutions and should be diluted in 10% glucose for intravenous use. The recommended therapeutic doses of both compounds deliver a substantial amount of sodium to the patient that should be calculated as part of the daily sodium requirement. A commercial, parenteral preparation of sodium benzoate plus sodium phenylacetate is available. Benzoate and phenylacetate should be used with caution in newborns with hyperbilirubinemia because they may displace bilirubin from albumin, although no documented case of kernicterus has yet been reported in infants so treated.

Hemodialysis should be started as an emergency procedure if the plasma ammonia level does not significantly decrease

Table 2 Treatment of acute hyperammonemia in an infant

Drug	Loading dose/infused over 1–2 h	Maintenance dose/continuous infusion–24 h
Sodium benzoate ^a	250 mg kg ⁻¹ (5.5 g m ⁻²)	250 mg kg ⁻¹ d ⁻¹ (5.5 g m ⁻²)
Sodium phenylacetate ^a	250 mg kg ⁻¹ (5.5 g m ⁻²)	250 mg kg ⁻¹ d ⁻¹ (5.5 g m ⁻²)
Arginine hydrochloride ^b (10%)	210–660 mg kg ⁻¹ (4.0–12.0 g m ⁻²)	210–660 mg kg ⁻¹ d ⁻¹ 4.0–12.0 g m ⁻²)

^aThese compounds are usually prepared as a 1–2% solution (10% glucose) for intravenous use; sodium from these drugs should be included as part of the daily sodium requirement.

^bThe higher dose is recommended in the treatment of patients with citrullinemia and argininosuccinic aciduria; arginine is not recommended in patients with arginase deficiency and in those for whom hyperammonemia is secondary to organic acidemia.

within 8 h. Exchange transfusion or peritoneal dialysis has little effect (ammonia clearance is about 10% of that of hemodialysis). Although hemodialysis clearly is the most effective measure, it is technically difficult to perform and may not be readily available. There is usually a dramatic decrease in the plasma ammonia level within a few hours of hemodialysis, and, in most patients, the plasma ammonia returns to normal within 48 h. In a patient whose hyperammonemia is due to an organic acidemia, hemodialysis effectively removes both the offending organic acid and ammonia from the body.

To minimize the possible production of ammonia by intestinal bacteria, oral administration of neomycin limits growth of intestinal bacteria that can produce ammonia. Oral lactulose acidifies the intestinal lumen, thereby reducing the diffusion of ammonia across the intestinal epithelium. Neither compound has been used extensively to treat acute hyperammonemia caused by inborn errors of metabolism in newborn infants.

There may be considerable lag between the normalization of ammonia and an improvement in the neurologic status of the patient. Several days may be needed before the infant becomes fully alert.

General Aspects of Long-Term Therapy

The goal of therapy is to provide a low-protein diet, arginine, and energy to promote growth and development, while preventing recurrent hyperammonemic crises. In general, all patients, regardless of the enzymatic defect, require some degree of protein restriction (1–2 g kg⁻¹ 24 h⁻¹). In patients with defects in the urea cycle, chronic administration of benzoate (250–500 mg kg⁻¹ 24 h⁻¹), phenylacetate (250–500 mg kg⁻¹ 24 h⁻¹), and arginine (200–400 mg kg⁻¹ 24 h⁻¹) or citrulline (in patients with OTC deficiency, 200–400 mg kg⁻¹ 24 h⁻¹) is effective in maintaining blood ammonia levels within the normal range. Phenylbutyrate may be used in place of phenylacetate because the patient and the family may not accept the latter owing to its offensive odor. A commercial preparation of the compound is available for oral use.

These compounds have been used during pregnancy without obvious teratogenic effect but the experience is still quite limited.

Growth parameters, especially head circumference, and nutritional indices (blood albumin, pre-albumin, pH, electrolytes, amino acids, zinc, and selenium) should be followed closely. Long-term care of these patients is best achieved by a team of experienced professionals (metabolic specialist, primary care physician, nutritionist, neurologist, and developmental pediatrician). Patients with urea cycle defects may develop a skin rash

resembling acrodermatitis enteropathica if they develop essential amino-acid deficiency, especially that of arginine, due to over-restriction of dietary protein. Catabolic states (infections and fasting) triggering hyperammonemia should be avoided or treated vigorously. In patients with urea cycle defects, acute hyperammonemic attacks may be precipitated by valproate administration. The use of this anticonvulsant should be avoided.

CPS and NAG Synthetase Deficiencies

Human CPS is the rate-limiting enzyme catalyzing the first step of ureagenesis. NAG is required for CPS activation. Patients with deficiencies of NAG or CPS can present as a devastating disease in neonates or as a more insidious late-onset condition. The severity of symptoms and its timing varies with the degree of enzyme deficiency and the metabolic environment. In near-complete deficiency, symptoms most commonly appear during the first few days of life when patients develop signs and symptoms of hyperammonemia such as poor feeding, vomiting, lethargy, increased intra-cranial pressure, convulsion, and coma. Late forms (as late as 32 years of age) may present as an acute episode of hyperammonemia (lethargy, vomiting, headache, disorientation, ataxia, seizures, and psychosis) in a seemingly normal individual and the onset of symptoms is often associated with increase in dietary protein intake, infection, stress, or exposure to medications such as valproate or steroids. Coma and death may occur during these episodes. Diagnostic confusion with migraine is frequent. Intermediate forms with mental retardation and chronic subclinical hyperammonemia interspersed with bouts of acute hyperammonemia have also been observed.

Laboratory findings include hyperammonemia. The plasma amino-acid analysis commonly shows a marked increase of glutamine and alanine with relatively low levels of citrulline and arginine. Urinary orotic acid is usually low or may be absent (see Figure 2). Patients with the late-onset form may have normal ammonia, plasma amino-acids, and urinary orotic acid levels when well, a finding that may confound diagnosis.

Treatment of acute hyperammonemic attacks (Table 2) and long-term therapy are discussed above. Patients with NAG synthetase deficiency benefit from oral administration of carbamylglutamate. Although deficiency of NAG synthetase is rare in North America, it is very important to differentiate this entity from CPS deficiency by assay of the enzyme activities in liver biopsy specimens or by gene sequencing.

Both CPS and NAG synthetase deficiencies are inherited as autosomal recessive traits. Both enzymes are normally present in liver and intestine. The CPS gene is mapped to chromosome

2q35. Several disease-causing mutations have been reported but genotype/phenotype correlations were not observed. The NAG synthetase gene is mapped to chromosome 17q21.31, and disease-causing mutations were reported in different families. The prevalence of these conditions is not known.

OTC Deficiency

It is the most common form of all the urea cycle disorders, comprising about 40% of all cases and is transmitted as an X-linked partially dominant trait. The clinical phenotype in affected males as well as heterozygous females shows a spectrum of severity ranging from neonatal hyperammonemic coma to asymptomatic adults.

Clinical manifestations in a male newborn usually are poor feeding, vomiting, lethargy, convulsions, and coma occurring in the first few days of life. Milder forms, which are commonly seen in heterozygous females and in some affected males, characteristically have episodic manifestations that may occur at any age (usually after infancy). Patients usually have episodes of hyperammonemia, and present with vomiting and neurologic abnormalities such as ataxia, mental confusion, agitation, and combativeness, which are separated by periods of wellness. These episodes usually occur after ingestion of a high-protein diet, exposure to medications such as valproate or steroids, or as a result of a catabolic state such as infection or fasting. Hyperammonemic coma, cerebral edema, and death may occur during one of these attacks. Mild-to-moderate mental retardation is common. Mild cerebral dysfunction may be present in asymptomatic female carriers. Gallstones have been seen in the survivors; the mechanism remains unclear.

The laboratory findings during the acute attack are hyperammonemia, and markedly elevated levels of glutamine and alanine, and decreased levels of citrulline and arginine. The blood level of urea (blood urea nitrogen (BUN)) is usually low. Elevation of the plasma concentrations of glutamine and alanine is secondary to hyperammonemia. A marked increase in the urinary excretion of orotic acid differentiates this condition from CPS deficiency (see [Figure 2](#)). In the mild form, patients may not have any abnormal laboratory findings. The diagnosis can be confirmed by performing an assay of enzyme activity that is normally present only in the liver or by mutational analysis of the OTC gene. About 20% of affected patients demonstrate a normal sequence, perhaps because the mutation involves an intron or a leader sequence. There are no prevalent mutations in the OTC gene and essentially every affected family has its own 'private' mutation. Prenatal diagnosis has been achieved by measuring the enzyme activity in the fetal liver tissue or by analysis of DNA studies in amniocytes or in chorionic villi samples. Obligate female carriers may be detected either by oral protein loading, which increases plasma ammonia and urinary orotic acid levels, or the allopurinol loading test, which increases the excretion of urinary orotic acid. A careful family history may reveal important clues that raise the possibility of OTC deficiency. A history of migraine or protein aversion is common in maternal female relatives of the proband. Indeed, careful scrutiny of the family history may reveal a pattern of unexplained deaths in male newborns in the maternal lineage.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are discussed above. Citrulline is preferred in place of arginine in patients with OTC deficiency. Patients with the severe form of disease may need early liver transplantation to prevent recurrent metabolic crisis and severe mental retardation.

The OTC gene has been mapped to chromosome Xp21.1. Many disease-causing mutations have been identified. Identifying the deleterious mutations helps to assess the severity of the disorder and select the most appropriate therapy. For example, patients with the most severe mutations, which result in profound enzyme deficiency, may need early liver transplant to prevent severe mental retardation or death. Mothers of affected infants are expected to be carriers of the mutant gene unless a *de novo* mutation has occurred. Gonadal mosaicism can explain the cause of having multiple affected offsprings in a mother with normal genotype.

Citrullinemia

Two clinically and genetically distinct forms of citrullinemia have been identified: citrullinemia type-I (classical form) is due to the deficiency of the AS enzyme and citrullinemia type-II (adult form) is due to deficiency of a mitochondrial transport protein named Citrin.

AS Deficiency (Citrullinemia Type I)

Citrullinemia type I is caused by the deficiency of AS (see [Figure 1](#)). The clinical phenotype varies based on the residual enzyme activity. The severe or neonatal form, which is most common, usually appears in the first few days of life. Affected infants typically appear normal at birth, but, as ammonia builds up in the body, they experience a progressive lethargy, poor feeding, vomiting, seizures, and loss of consciousness. In the subacute or mild form, clinical findings such as failure to thrive, frequent vomiting, intense headaches, ataxia, and developmental delay develop after 1 year of age.

Episodes of hyperammonemia, triggered by an intercurrent catabolic state, may bring the diagnosis to light.

Laboratory findings are similar to those found in patients with OTC deficiency, except that the plasma citrulline concentration is markedly elevated (50–100 times normal) in patients with citrullinemia type I (see [Figure 2](#)). Urinary excretion of orotic acid is moderately increased. The diagnosis is confirmed by assay of enzyme activity in cultured fibroblasts or by mutation analysis. Prenatal diagnosis is possible by assay of enzyme activity in amniotic fluid or by mutation analysis of cultured chorionic villus cells.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are outlined earlier in this article. Although prognosis is poor for symptomatic neonates, patients with the mild disease usually do well on a protein-restricted diet in conjunction with sodium benzoate, phenylbutyrate, and arginine therapy. Mild-to-moderate mental deficiency is a common sequela, even in a well-treated patient. Liver transplant should be considered in patients with the severe form of this disease.

Citrullinemia is inherited as an autosomal recessive manner. The gene is located on chromosome 9q34.1. Several

disease-causing mutations have been identified in different families. The majority of patients are compound heterozygotes for two different alleles. The prevalence of the condition is not known. The recent introduction of neonatal screening for urea cycle defects has disclosed affected patients, who are ostensibly asymptomatic, even with ingestion of a regular diet. It is unclear at present whether stringent dietary protein restriction is necessary in these infants. Long-term follow-up is needed.

Citrin Deficiency (Citrullinemia Type II)

Citrin is a mitochondrial transport protein encoded by a gene (*SLC25A13*) located on chromosome 7q21.3. One of the functions of this protein is to transport aspartate from mitochondria to the cytoplasm; aspartate is required to convert citrulline to argininosuccinic acid (see [Figure 1](#)). If aspartate is unavailable to the cytoplasm, urea will not be formed at a normal rate and citrulline will accumulate. Patients with citrin deficiency have decreased AS activity in the liver but they do not have any mutations/deletion in their AS gene. It is postulated that citrin deficiency or its mutated gene interferes with translation of the messenger RNA for AS. The condition initially was reported almost exclusively among Japanese individuals but a few non-Japanese patients have also been identified. There are two phenotypes of citrin deficiency: (1) neonatal intrahepatic cholestasis (citrullinemia type II–neonatal form) and (2) citrullinemia type II (adult form–CTLN2). The pathogenesis of citrullinemia type II (neonatal and adult forms) remains enigmatic.

Neonatal intrahepatic cholestasis (citrullinemia type II–neonatal form)

Clinical symptoms and signs usually start in the first 3 months of age and disappear by age 1 year with appropriate treatment. The findings are intrahepatic cholestasis, diffuse fatty liver and parenchymal cellular infiltration associated with hepatic fibrosis, growth retardation, marked hypoproteinemia, increased prothrombin time and partial thromboplastin times, hemolytic anemia, and hepatomegaly. Patients may have elevated galactose detected through newborn screening but all enzymes involved in galactose metabolism are normal. The reason for hypergalactosemia is probably liver dysfunction. Although the condition is almost exclusively seen in Japan, the diagnosis should be considered in cases of unexplained neonatal hepatitis with cholestasis. Data on the long-term prognosis and the natural history of the condition are limited; development into the adult form of the condition (see later) after several years of seemingly asymptomatic hiatus has been observed.

Citrullinemia type II, adult form (adult-onset citrullinemia, citrullinemia type II–mild form)

Citrullinemia type II is an adult-onset disease, which starts suddenly in a previously normal individual at around 20–50 years of age, and manifests with recurring episodes of hyperammonemia, neuropsychiatric symptoms including nocturnal delirium, aggression, irritability, hyperactivity, delusions, disorientation, aberrant behavior, tremors, and frank psychosis. Patients usually have hyperammonemia and moderately elevated citrulline. Patients who recover from the first episode will have recurrent attacks and most will die within a few years of diagnosis, mainly from cerebral edema. Pancreatitis,

hyperlipidemia, and hepatoma are major complications among the survivors. Many individuals with citrullinemia type II have a strong preference for protein-rich and/or lipid-rich foods, and an aversion to carbohydrate-rich foods. Medical treatment has been mostly ineffective for prevention of future attacks. Indeed, some have speculated that the administration of large amounts of glucose might even prove deleterious, because the citrin transporter is important to the metabolism of glucose. Liver transplantation is the most effective therapy.

Several disease-causing mutations of the gene have been identified in affected families in Japan. Although the frequency of an abnormal gene is quite high in Japan (1:20 000 homozygosity), the clinical condition has a frequency of only 1:100 000. This indicates that a substantial number of homozygous individuals remain asymptomatic. Only a few non-Japanese patients have been identified.

AL Deficiency (Argininosuccinic Aciduria)

There is considerable phenotypic variability. The most severe cases present in the neonatal period with lethargy, vomiting, poor suck, hypothermia, hepatomegaly, and progressive encephalopathy. Mortality is high and neurologic damage is frequent in survivors. The disease may also be manifested later in childhood (subacute or late form) with an acute encephalopathy that often is precipitated by infection or high-protein intake. Patients may also display chronic symptoms such as episodic vomiting, mental status changes, lethargy, and behavioral abnormalities associated with hyperammonemia. Mild-to-moderate developmental delay and seizures can be seen even in patients without a documented history of hyperammonemia. Abnormalities of the hair characterized by dryness and brittleness are of special diagnostic value (trichorrhexis nodosa). Gallstones have been seen in some of the survivors.

Laboratory findings include hyperammonemia, moderate elevations in liver enzymes, nonspecific increases in plasma levels of glutamine and alanine, moderate increase in plasma levels of citrulline, and marked increase in plasma levels of argininosuccinic acid (see [Figure 2](#)). In most amino acid analyzers, argininosuccinic acid appears as series of anhydrides within the isoleucine or methionine region, which may cause confusion in the diagnosis. Argininosuccinic acid can also be found in large amounts in urine and spinal fluid. The levels in the spinal fluid are usually higher than those in plasma. The enzyme is normally present in red blood cells, the liver, and cultured fibroblasts. Prenatal diagnosis is possible by measurement of enzyme activity in cultured amniotic cells or by identification of the mutant gene. Argininosuccinic acid is also elevated in the amniotic fluid of affected fetuses. This deficiency is inherited as an autosomal recessive trait. Several mutations were reported throughout the gene, but there were no genotype/phenotype correlations.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are outlined earlier in this article. Mental retardation, persistent hepatomegaly with mild increases in liver enzymes, and bleeding tendencies due to abnormal clotting factors are the common sequelae of the disease. Liver transplantation should be considered in patients with the severe form of the disease.

Arginase Deficiency (Hyperargininemia)

There are two genetically distinct arginases in humans. One is cytosolic (A1) and is expressed in the liver and erythrocytes, and the other (A2) is found in renal and brain mitochondria. The gene for the cytosolic enzyme, which is deficient in patients with arginase deficiency, is mapped to chromosome 6q23. The role of the mitochondrial enzyme is not well understood; its activity increases in patients with argininemia but has no protective effect. Several disease-causing mutations have been identified in different families. Arginase deficiency is inherited as an autosomal recessive trait.

The clinical findings are nonspecific and are quite different from those of other urea cycle enzyme defects. The patients usually remain asymptomatic in the first few months or, sometimes, years of life. A progressive spastic diplegia, choreoathetotic movements, and loss of developmental milestones in a previously normal infant are usually the initial signs and symptoms. Mental retardation is progressive; seizures are common, but episodes of severe hyperammonemia are not usually seen. Hepatomegaly may be present. The acute neonatal form with intractable seizures, cerebral edema, and death has also been reported.

Laboratory findings include three- to fourfold elevation of the plasma and cerebrospinal fluid (CSF) arginine concentration (see [Figure 2](#)). Urinary orotic acid is moderately increased. Plasma ammonia levels may be normal or mildly elevated. Urinary excretions of arginine, lysine, cystine, and ornithine are usually increased, but normal levels have also been noted. Therefore, determination of amino acids in plasma is a critical step in the diagnosis of argininemia. The diagnosis is confirmed by assaying arginase activity in red blood cells or mutation analysis. Patients can be detected with newborn screening.

The mainstay of treatment is a low-protein diet. Administration of a synthetic protein made of essential amino acids usually results in a dramatic decrease in plasma arginine concentration and an improvement in neurologic abnormalities. The composition of the diet and the daily intake of protein should be monitored by frequent plasma amino-acid determinations. Sodium benzoate or sodium phenylbutyrate ($250\text{--}375\text{ mg kg}^{-1}\text{ 24 h}^{-1}$) is also effective in controlling hyperammonemia, when present; lowering of plasma arginine levels has been noted with this treatment. Mental retardation is a common sequela of the condition.

Transient Hyperammonemia of the Newborn

Transient hyperammonemia of unknown cause may be a relatively common variety of neonatal hyperammonemia. Most affected infants are premature and have mild respiratory distress syndrome. Hyperammonemic coma may develop within 24 h of life, and the infant may succumb to the disease if treatment is not started immediately. Laboratory studies reveal marked hyperammonemia, and plasma levels may be as high as $4000\text{ }\mu\text{mol l}^{-1}$. Treatment should be initiated promptly and continued vigorously (see earlier). Recovery without sequelae is common, and hyperammonemia does not recur even with a normal protein diet.

Gyrate atrophy of the retina and choroid

Ornithine is one of the intermediate metabolites of the urea cycle that is not incorporated into natural proteins. Rather, it is generated in the cytosol from arginine and must be transported into the mitochondria, where it is used as a substrate for the enzyme OTC to form citrulline. Excess ornithine is catabolized by two enzymes, ornithine 5-aminotransferase, which is a mitochondrial enzyme and converts ornithine to a proline precursor, and ornithine decarboxylase, which resides in the cytosol and converts ornithine to putrescine (see [Figure 1](#)).

The deficiency of the enzyme ornithine 5-aminotransferase causes gyrate atrophy of the retina and choroid. It is a rare, autosomal recessive disorder (see [Figure 1](#)). About 30% of the reported cases are from Finland. The initial clinical findings are myopia and reduction of peripheral vision and in some patients, reduction of night vision in the first decade of life. Almost all patients demonstrate impaired peripheral vision by age 10 years. Loss of visual function progresses to complete blindness by the fourth decade of life. Atrophic lesions in the retina resemble cerebral gyri. These patients usually have normal intelligence; however, early degenerative and atrophic brain changes and abnormal electroencephalographs (EEGs) were reported in some patients.

There are markedly elevated levels (10- to 15-fold) of ornithine in plasma and other body fluids. The goal of treatment is to reduce high ornithine levels. Pyridoxine therapy may decrease plasma ornithine levels and is recommended for all newly diagnosed patients at a dose of $300\text{--}600\text{ mg d}^{-1}$ for a 2-week trial. Arginine (precursor of ornithine) restriction also helps to decrease ornithine levels. On average, protein foods contain 4–6% arginine. A low-protein diet may be supplemented with essential amino acids. Severe arginine restriction may cause hyperammonemia. The gene for ornithine 5-aminotransferase is mapped to chromosome 10q26. Many disease-causing mutations have been identified in different families.

Hyperammonemia–Hyperornithinemia–Homocitrullinemia Syndrome

Hyperammonemia–hyperornithinemia–homocitrullinemia (HHH) syndrome is a rare autosomal recessive disorder in which there is defective transport of ornithine from the cytosol into the mitochondria, resulting in accumulation of ornithine in the cytosol, and its deficiency in mitochondria. The intramitochondrial deficiency results in condensation of carbamoylphosphate with lysine rather than ornithine (the usual co-reactant in the ornithine transcarbamylase reaction) and production of homocitrulline ([Figure 1](#)). Intramitochondrial ornithine deficiency, due to the transport defect, results in a functional deficiency of OTC and OAT activities. There is a wide spectrum of clinical manifestations. Hyperammonemia may develop shortly after birth or may be delayed until adulthood. Acute episodes of hyperammonemia manifest as refusal to feed, vomiting, and lethargy; coma may occur during infancy. Progressive neurologic signs, such as lower limb weakness, increased deep tendon reflexes, spasticity, clonus, seizures, and varying degrees of psychomotor retardation may develop if the condition remains undiagnosed. Coagulopathy, especially factor VII and

X deficiencies, has been reported in some patients. No clinical ocular findings have been observed in patients with HHH.

The triad of hyperornithinemia, homocitrullinuria, and hyperammonemia is a pathognomonic laboratory finding. Plasma ornithine level is 3–10 times higher than normal and tends to be lower than that seen in patients with gyrate atrophy of the retina and choroid.

Restriction of protein intake improves hyperammonemia. Ornithine supplementation may produce clinical improvement in some patients. The gene for this disorder (*SLC25A15*) is located on chromosome 13q14. Several mutant alleles have been reported in the literature. The F188 deletion is the most common mutation in patients of French Canadian ancestry. No genotype and phenotype correlation has been observed.

Glossary

Active transport Use of energy to transport a substance, often across membranes from an area where it is in lower concentration to an area where it is in higher concentration. Membrane proteins called transporters perform active transport.

Endocytosis Ingestion of particulate matter or fluid by phagocytosis or pinocytosis; that is, bringing material into a cell by invagination of its surface membrane and then pinching off the invaginated portion to form a vesicle, endosome, or vacuole.

Hydrolases Enzymes that act as catalysts in the cleavage of covalent bonds with accompanying addition of water. Lipases are hydrolases that break down fatty acids and other lipids. Proteases specifically digest peptide bonds.

Multi-vesicular body (MVB) A specific subset of late endosomes defined as containing intra-luminal vesicles

(ILVs) created by the endosomal sorting complexes required for transport (ESCRT) pathway. Transmembrane receptors destined for degradation are packaged into the ILVs, and when the MVBs undergo fusion with the vacuole, they are degraded.

Vacuole A large, membrane-bound cytoplasmic organelle that functions in ingestion, digestion, excretion, and storage of water, sugars, proteins, lipids, ions, and other materials. Vacuoles and vacuole-related organelles are found in fungal, plant, protozoan, and mammalian cells. Most plant cells have a single vacuole that takes up much of the cell and helps maintain the shape/turgor of the cell.

Vesicular transport Trafficking of proteins and lipids from one cellular compartment to another by means of membrane-enclosed intermediates such as endosomes or organelle fragments.

Identification/Discovery of Vacuoles and Vacuolar Constituents

Vacuoles were first described in early microscopy studies on plant and protozoan cells in the mid-nineteenth century. Felix Dujardin conceived the term ‘vacuole’ in 1835 to describe large translucent regions in cells surrounded by a membrane that were devoid of cytoplasm. Subsequent studies in the late nineteenth century revealed that vacuoles were not simply devoid, but serve as storage sites for water, sugars, and salts. In 1955, Christian de Duve coined the term ‘lysosomes’ to describe vacuole-like compartments containing acid hydrolases in mammalian cells. Shortly after, independent cell morphological studies undertaken by the Palade and Novikoff laboratories revealed that lysosomes appear as organelles with varying diameters (0.1–1.0 μm) and with heterogeneous morphologies, containing electron-dense cores and in some cases internal vesicles. In the yeast *Saccharomyces cerevisiae*, vacuoles are larger with respect to cell size, but display similar characteristics in terms of electron density and intraluminal vesicles, when observed under certain conditions (Figures 1(a) and 1(b)).

Biochemical studies performed by de Duve and colleagues initially identified lysosomes as organelles of highly buoyant centrifugal properties that exhibited hydrolytic activities. The hydrolases within isolated lysosomes demonstrated latent activity, dependent on the integrity of their surrounding membrane. Specifically, hydrolase activity was retained within the limiting vacuole/lysosome membrane, restricted from the cell lysate unless the limiting membrane was disrupted. Since vacuoles/lysosomes are morphologically heterogeneous, biochemical studies have formed the current definition of vacuoles/lysosomes as membrane-bound acidic organelles that contain mature acid-dependent hydrolases and certain integral membrane glycoproteins (termed LAMPs, lysosomal-associated membrane proteins). Vacuoles lack other proteins that distinguish them from endosomes (compartments that deliver material to vacuoles), such as biosynthetic sorting receptors (such as the mannose 6-phosphate receptor and sortilin) and recycling cell-surface receptors (such as transferrin).

As mentioned, vacuoles/lysosomes are membrane compartments that serve as a major degradative compartment in eukaryotic cells. Both endogenous and exogenous molecules can be delivered to vacuoles through biosynthetic and

Figure 1 Ultrastructural analysis of vacuole morphology in wild-type (a) and hydrolase-deficient (b) yeast cells reveals electron-dense cores and intraluminal membrane vesicles, respectively. (a) Wild-type cells were grown to mid-log phase, fixed, and visualized by electron microscopy. Vacuoles appear as dark, electron-dense organelles due to the accumulation of cellular proteins, lipids, and other molecules. (b) In cells lacking vacuolar ATPase activity (*vma4Δ* mutant cells), vacuoles appear translucent by electron microscopy and contain intraluminal vesicles. (Inset) High magnification image of vacuolar vesicles (arrowheads). v, vacuoles; n, nucleus; m, mitochondria. Scale = 0.1 μm . Reproduced from Wurmser A and Emr SD (1998) Phosphoinositide signaling and turnover: PtdIns(3)P, a regulator of membrane traffic, is transported to the vacuole and degraded by a process that requires luminal vacuolar hydrolase activities. *EMBO Journal* 17: 4930–4942, copyright 1998.

endocytic pathways. In addition, vacuoles can degrade cytoplasmic proteins via a process termed ‘autophagy’. The degradative function of these organelles is carried out by numerous acid-dependent hydrolases (e.g., proteases, lipases, and glycosidases) contained within its lumen (Figure 2). The outer, limiting membrane of vacuoles/lysosomes also contains a set of highly glycosylated, vacuolar/lysosomal-associated membrane proteins (LAMPs), many with unknown functions (Figure 2). Additional vacuolar membrane proteins mediate transport of ions, amino acids, and other solutes across the vacuolar membrane and maintain an acidic luminal pH in the range of 4.5–6.5 (Figure 2).

Vacuole Function in Yeast

The vacuole of the yeast *S. cerevisiae* plays important roles in protein degradation, pH regulation, ion homeostasis, nutrient storage, and stress responses. Degradation is mediated by a large number of hydrolases that reside within the vacuole (proteases, lipases, and glycosidases; Figure 2) with various substrate specificities. Thus, it is a major site for degradation of cellular proteins, lipids, and even whole organelles.

A remarkable feature of vacuoles is their acidification. In yeast, a specific vacuolar proton pump ATPase (V-ATPase) mediates this process. Biochemical and genetic approaches have identified 14 subunits of the V-ATPase (encoded by the VMA genes for vacuolar membrane ATPase). These 14 subunits comprise two functional subcomplexes: the peripheral V_1 subcomplex, responsible for ATP hydrolysis, and the V_0 subcomplex, responsible for proton translocation across the membrane (Figure 2). Cells lacking a functional V-ATPase are viable, but require an intact endocytic pathway to the vacuole and fail to grow on media with neutral pH, indicating that vacuole acidification is an essential feature. Consistent with this, the electrochemical gradient generated by the V-ATPase is necessary to drive several other transport systems described below (Figure 2).

In addition to its hydrolytic functions, the vacuole serves as a storage compartment for several ions, nutrients, and metabolites (Figure 2). For example, the Vcx1 protein acts as a high-capacity $\text{H}^+/\text{Ca}^{2+}$ exchanger in the regulation of vacuolar calcium flux (Figure 2). The vacuole also stores both phosphate and polyphosphate (Figure 2). Since hydrolysis of phosphate leads to the release of protons, a role for polyphosphate in pH homeostasis has been suggested. Polyphosphate is proposed to function as a cation counter-ion as well. In addition, the vacuole membrane possesses ABC family transporters that sequester toxic metals and metabolites away from the cytoplasm (Figure 2). Basic and neutral amino acids are also stored inside the vacuole at high concentrations. For example, arginine accumulates in vacuoles at concentrations an order of magnitude greater than in the surrounding media (Figure 2). Consistent with this, several H^+ /amino acid antiporter systems have been identified in yeast. Pools of amino acids stored in the vacuole may be utilized during nitrogen starvation.

Vacuole Biogenesis and Transport Pathways to the Vacuole in Yeast

To carry out the numerous functions that vacuoles perform, several membrane trafficking pathways deliver cellular components to vacuoles. Model genetic systems such as the yeast *S. cerevisiae* have been instrumental in identifying both proteins and lipids that constitute components of vacuoles and the machinery involved in transport to vacuoles. Importantly, many of these factors and trafficking pathways are conserved in mammalian cells.

At least eight pathways have been identified in vacuole biogenesis and vacuolar protein trafficking in yeast: endocytosis from the cell surface, two distinct biosynthetic pathways from the Golgi (the vacuolar protein sorting (Vps) and AP-3

Figure 2 Schematic overview of vacuolar functions and components. The vacuole lumen possesses several hydrolase activities and accumulates ions, such as phosphate (PO_4^-) and polyphosphates. Lysosomal membranes also contain integral transmembrane proteins termed LAMPs. The vacuolar ATPase (V_0/V_1) functions as the primary proton pump that generates an electrochemical gradient used to drive other vacuole membrane transport systems, such as arginine (Arg) and divalent cation (Ca^{2+}) anti-transporters. Toxic metals and metabolites are sequestered in the vacuole by ABC family transporters.

pathways), multivesicular body (MVB) sorting, the cytoplasm to vacuole pathway (Cvt), macro-autophagy, micro-autophagy, and vacuole inheritance during cell division (Figure 3(a)). The endocytic pathway is essential for regulating levels of cell-surface signaling receptors and removal of damaged transmembrane proteins and lipids. The endocytic and Vps pathway intersect at a late endosomal compartment. Components of the Vps sorting pathway are directly involved in vacuolar biogenesis, morphology, and function, as discussed in greater detail below. Alkaline phosphatase (ALP) travels from the Golgi to the vacuole along the AP-3 sorting pathway that is partially independent of the Vps and endocytic pathways. Proteins such as aminopeptidase I (API) are delivered from the cytoplasm to the vacuole through pathways involving products of the *ATG* (autophagy) genes. In micro-autophagy, the vacuole membrane invaginates to engulf cytoplasmic material, including entire organelles such as peroxisomes. Vacuolar segregation into dividing daughter cells of budding yeast requires *VAC* (vacuolar inheritance) genes, some of which also participate in the Vps pathway. Previous studies have also identified several distinct factors involved in vacuolar inheritance.

The Vps Pathway

Carboxypeptidase Y (CPY) is the prototype of a subset of proteins that traffic from the Golgi to the vacuole via an endosomal intermediate (Figure 3(a)). This pathway depends on the function of over 60 *VPS* gene products, mutations in which result in the mis-sorting of CPY to the secretory pathway, abnormal vacuole morphology, and, in some cases, abnormal endosome morphology. In a manner analogous to receptor-mediated sorting in mammalian cells, the CPY receptor Vps10 (the prototype of the

sortilin family) binds CPY at the Golgi via a targeting signal. Sorting of this receptor–ligand complex into vesicles destined for endosomes requires the coat protein clathrin and accessory factors including the AP-1 clathrin adaptor complex, the Gga proteins, and a dynamin family guanosine triphosphatase (GTPase) (Vps1). The class D Vps proteins are involved in CPY vesicle targeting and fusion with endosomes, such as Vps21 (Rab5 homolog), Vps9 (Rab GEF), Vac1 (EEA1), Vps45 (Sec1 homolog), Pep12 (t-soluble NSF attachment protein (SNAP) receptor (t-SNARE)), the class C core vacuole–endosome transport (CORVET) complex (consisting of class D and C Vps proteins), and Sec18 (NSF). The Vps34 PI 3-kinase also contributes to endosomal targeting and maturation by the generation of the phosphoinositide lipid PI3P that recruits effector proteins such as the Fab1, YGLO23, Vps27, and EEA1 (FYVE) domain-containing protein Vac1. At the endosome, Vps10 dissociates from CPY and recycles to the Golgi in a process requiring the retromer complex (consisting of Vps29, Vps26, Vps35, Vps5, and Vps17). Interestingly, PI3P also mediates endosomal recycling through the recruitment of the PX domain-containing proteins Vps5 and Vps17. Mutants defective in retromer function mis-localize Vps10 to the vacuole membrane and secrete CPY, as Vps10 becomes limiting for subsequent sorting reactions at the Golgi.

Another set of Vps proteins, the class E Vps proteins, form the endosomal sorting complexes required for transport (ESCRT) complexes necessary for sorting transmembrane proteins at the endosome and the formation of multi-vesicular bodies (MVBs). Recent attention has been paid to this pathway because of the elucidation of the ESCRT protein complexes, which are necessary for the downregulation of internalized cell-surface signaling receptors and damaged plasma membrane proteins destined for vacuolar degradation (Figure 4).

Figure 3 (a) Model representation of the transport pathways to the yeast vacuole. Endocytosis of cell-surface proteins is followed by transport to early endosomes and then late endosomes. The Vps pathway sorts proteins (Vps10 and precursor CPY) from the late Golgi to the late endosome. At the late endosome, ubiquitinated cargo is sequestered into intraluminal vesicles by the ESCRT pathway to form multivesicular bodies (MVBs), while other proteins, such as the Vps10 sorting receptor, are recycled to the Golgi via the retromer pathway. The AP-3 pathway functions as a Golgi to vacuole route that is independent of the late endosome/MVB. In the Cvt pathway, cytoplasmic proteins are enclosed within double membrane structures that subsequently fuse with and deliver their material into the vacuole. Macro-autophagy is similar to the Cvt pathway but is induced primarily under starvation conditions. In micro-autophagy, the vacuole membrane invaginates to mediate the uptake of cytoplasmic material. (b) Schematic diagram of proteins that function in the final docking/fusion step of various cargo vesicles to the vacuole. SNARE proteins (Vam3, Vam7, and Ykt6) are represented by rounded rectangles. Components of the class C Vps complex (Vps11, 16, 18, 33, 39, and 41) that mediate SNARE pairing are shown. Tethering is also mediated by the Rab-like GTPase, Ypt7, and the Mon1/Ccz1 protein complex.

The ESCRT complexes function sequentially on the endosomal surface as discrete modules (elegantly numbered ESCRTs 0, I, II, and III) to bind, cluster, and envelope ubiquitinated transmembrane proteins into the intra-luminal vesicles that bud into the MVB. Cells lacking ESCRT function accumulate abnormal/aberrant endosomes containing both biosynthetic cargoes such as CPY and endocytosed transmembrane proteins. The abnormal/exaggerated endosomes observed in these mutant cells form in part due to impaired MVB vesicle budding into the lumen of the endosome.

Fusion of late endosomes/MVBs with the vacuole requires another set of proteins including Ypt7 (Rab7 homolog) and SNARE proteins (Vti1, Ykt6, Nyv1, Vam7, and Vam3). The

class C Vps protein complex (also termed homotypic vacuolar fusion and protein sorting (HOPS)) consisting of Vps18, Vps11, Vps16, Vps33 (Sec1 homolog), Vps41, and Vps39 (Rab GEF) is required for this final fusion step as well (Figure 3(b)). The Mon1/Ccz1 protein complex has been shown to bind the Rab GTPase Ypt7 in the progression of endosomal maturation and vacuolar targeting. The Vps34 PI 3-kinase also contributes to this fusion step by the generation of PI3P that recruits effector proteins such as the PX domain-containing protein Vam7, and thus PI3P mediates several steps involved in endosomal sorting, maturation, and fusion in route to the vacuole. Mutants with defects in the class C Vps gene products accumulate numerous endosomal intermediates and MVBs that fail to

Figure 4 The ESCRT complexes mediate delivery of ubiquitinated cargo to the vacuole/lysosome. Schematic of ESCRT-0, -I, -II, and -III complexes and Vps4 on the late endosome surface. For simplicity, the yeast names for the ESCRT subunits have been used. Once at the endosome, ubiquitinated cargo is recognized by a ubiquitin-interacting motif in ESCRT-0 subunit Vps27. ESCRT-I and -II also bind ubiquitin directly and function as cargo sorting and clustering agents. ESCRT-II also initiates ESCRT-III assembly by a Vps25–Vps20 interaction. Snf7 polymerization is associated with membrane deformation, allowing ESCRT-III to envelope cargo and package it into intra-luminal vesicles that bud into the endosome interior. Finally, Vps2 recruits the AAA ATPase Vps4, which can disassemble the ESCRT machinery for a new round of cargo sequestration. Adapted with permission from Elsevier Limited: *Cell* 137: 181–182, copyright 2009.

fuse with the vacuole. Accordingly, mutants defective in components of the vacuolar fusion machinery display highly fragmented vacuoles and can sometimes even lack vacuoles entirely.

The AP-3 Pathway

ALP is an integral membrane protein that traffics from the Golgi to the vacuole independently of endosome/MVB compartments that transport CPY and endocytic cargoes (Figure 3(a)). A specific adaptor complex, termed AP-3, mediates sorting of ALP into vesicles at the Golgi. However, following formation, fusion of ALP cargo vesicles with the vacuole is dependent on the class C Vps complex, Ypt7, Vam7, and Vam3. Thus, the AP-3 and Vps pathways converge upon common docking/fusion machinery at the vacuole (Figure 3(b)). The mechanism for the convergence, and the reason why AP-3 vesicles fuse with the vacuole, but not with endosomes containing CPY, is still unclear.

Cytoplasm to Vacuole Transport and Macro-Autophagy

Autophagy is a trafficking pathway to vacuoles regulated by changes in nutrient availability. During starvation-induced macro-autophagy, cytoplasmic material is first sequestered in double-membrane vesicles called autophagosomes and then subsequently delivered to the vacuole (Figure 3(a)). While autophagy is induced, the cytoplasm-to-vacuole targeting (Cvt) pathway constitutively packages the hydrolases aminopeptidase I (API) and α -mannosidase into autophagosomes for delivery to vacuoles. Autophagosomes are targeted to, and fuse with, the vacuole by the same machinery that mediates endosome-vacuole fusion (Figure 3(b)). Inside the vacuole, the lipase Atg15 is responsible for autophagosome turnover (Figure 2). Atg15 may also participate in the turnover of intra-luminal vesicles formed by the ESCRT-mediated MVB pathway. In mammalian cells, fusion of autophagosomes with lysosomes results in intermediate compartments termed ‘auto-lysosomes’.

Vacuole/Lysosome Functions in Higher Eukaryotes

The Contractile Vacuole in Protozoa

Protozoa living in freshwater exist in a hypotonic environment. Water flows across their plasma membrane since their cytosol is hypertonic to the environment. To adapt, many protozoa have an organelle, the contractile vacuole complex (CVC), which collects and expels excess water. Previous work shows that CVCs are composed of a central vacuole with radial arm-like extensions. The extensions are often divided into separate bundles of tubules and contain proton-translocating V-ATPase enzymes that provide an electrochemical gradient necessary for fluid collection. The membrane of the central compartment lacks V-ATPases, but can expand into a reservoir for fluid storage, and is capable of fusing with the plasma membrane. It is then that the central compartment undergoes contraction, resulting in fluid expulsion. The exact mechanism of this contraction is unknown, but it has been proposed that in *Dictyostelium* a class of membrane sculpting proteins, the mental retardation GTPase-activating proteins (GAPs) (MEGAPs), polymerizes on the contractile vacuole and use their membrane bending F-BAR domains to squeeze water out of the organelle.

Lysosome-Related Organelles

The mammalian vacuole-like lysosome also is a site for delivery of cellular materials targeted for degradation, as it is the terminal compartment of the endocytic, biosynthetic, phagocytic, and autophagy pathways in mammalian cells. However, the idea that vacuoles/lysosomes are simply degradative sites has evolved. This is partly due to the identification of lysosome-like compartments that perform additional cellular functions, such as lysosomes that secrete their contents after fusion with the plasma membrane. Many properties of vacuoles/lysosomes are shared with this group of cell type-specific lysosome-related organelles, which include melanosomes (pigment granules), lytic granules, platelet-dense granules, basophil granules,

Table 1 Disorders associated with lysosomal dysfunction

<i>Disease</i>	<i>Defective protein(s)</i>	<i>Manifestations and lysosomal defects</i>
<i>Examples of inherited lysosomal storage diseases</i>		
I-cell disease	GlcNAc-phosphotransferase	Multiple lysosomal enzymes are secreted. Cells are highly vacuolated and contain numerous dense inclusion bodies
Tay–Sachs disease	β -Hexosaminidase	Neuronal GM2 gangliosidosis
Pompe's disease	α -Glucosidase	Glycogen storage disease type II
Gaucher's disease	β -Glucosidase	Sphingolipid metabolism defects
Niemann–Pick disease type A	Sphingomyelinase	Sphingolipid and cholesterol metabolism defects. Accumulation of lipid-storing foam cells. In the brain, neurons are highly vacuolated
Hermansky–Pudlack syndrome	AP-3 complex subunits, HOPS complex subunits	Defects in lysosome-related organelle biogenesis, particularly melanosomes and dense granules
Danon disease	LAMP2	Chaperone-mediated autophagy and macro-autophagy defects
Osteopetrosis	CLC7, OSTM1	H ⁺ /Cl [−] anti-transporter defects. Lysosomal acidification defects
<i>Disease</i>	<i>Defective protein(s)</i>	<i>Manifestations and endo-lysosomal defects</i>
<i>Neurodegenerative disorders associated with lysosomal defects</i>		
Alzheimer's disease	APP, PS, SORL-1, Cathepsin D	Autophagy defects, accumulation of dense inclusion bodies
Parkinson disease	α -Synuclein, hVps24 (ESCRT-III subunit)	Autophagy defects, MVB/ESCRT pathway defects
Huntington disease	Htt, hVps24 (ESCRT-III subunit)	Autophagy defects, MVB/ESCRT pathway defects
Amyotrophic lateral sclerosis (ALS)	Rab5, hVps2 (ESCRT-III subunit)	Endosomal and MVB sorting defects
Frontotemporal dementia (FTD-3)	hVps2 (ESCRT-III subunit)	Endosomal and MVB sorting defects, accumulation of aberrant autophagosomes
Charcot–Marie–Tooth disease 2B	Rab7 (Ypt7 ortholog)	Endosomal sorting defects
Niemann–Pick disease type C	NPC1, NPC2	Sphingolipid and cholesterol transport defects. Endosomal and autophagy defects
Batten disease	CLN-1, CLN-2, CLN-3, CLN-7	Neuronal lipofuscinosis (NCL). Impaired lysosomal degradation and autophagy defects

nuetrophil granules, and dendrocyte major histocompatibility complex class II compartments (involved in antigen presentation). However, in addition to lysosomal proteins, these organelles contain cell type-specific components that are responsible for their specialized functions.

Pathogen-Containing Vacuoles

The uptake of foreign objects by macrophages often provides an important line of immune defense. In addition, autophagy is a key pathway in the innate immune response, as auto-lysosomes are the sites for degradation of intracellular pathogens. For some intracellular pathogens (including viruses, bacteria, and protozoa), however, phagocytosis represents an opportunity to gain protected access within a host cell. Other types of pathogens, including *Salmonella* and *Shigella*, actively invade host cells by delivering effectors into the host cell that leads to their direct uptake into intracellular vacuoles. Regardless of the mode of entry, the resulting intracellular vacuole that contains the parasite undergoes a maturation process, involving numerous membrane trafficking events, as well as transmembrane transport of nutrients. Maturation of the vacuole yields a unique intracellular environment where the parasites are not only provided with essential nutrients, but also protected from destruction by the host. Interestingly, many bacterial pathogens encode phosphoinositide-binding proteins as well as regulatory proteins to modulate PI3P levels

on pathogen-containing vacuoles, thus impairing fusion with host cell lysosomes.

Diseases Associated with Lysosomal Disorders

Several human genetic disorders are associated with defects in vacuolar/lysosomal hydrolase function and transport, such as I-cell, Tay–Sachs', Pompe's, Gaucher's disease, and Niemann–Pick disease types A and B (Table 1). I-cell disease is manifested by the inappropriate targeting/transport of multiple lysosomal enzymes. Cells of these patients become highly vacuolated and contain numerous dense inclusion bodies. Patients with I-cell disease display severe clinical defects including skeletal and neurological defects, delayed growth and psychomotor development, and often death before age 5. Abnormalities in the AP-3 pathway and traffic to lysosome-related organelles have also been observed in human genetic diseases such as the Chediak–Higashi and Hermansky–Pudlak syndromes (Table 1). Moreover, lysosomes and auto-lysosomes are sites of degradation for mis-folded or damaged transmembrane and cytoplasmic proteins. As such, defects in both the ESCRT and autophagy pathways have been implicated in neurodegenerative diseases (Table 1). The similarity of genes affected in these lysosomal diseases to genes involved in vacuolar transport in yeast further demonstrates the importance of understanding the molecular machinery involved in the biogenesis and function of vacuoles, lysosomes, and lysosome-related organelles.

Further studies on vacuole biogenesis will likely shed light on additional aspects of vesicular transport in the endosomal, lysosomal, and secretory systems.

Vascular Endothelial Growth Factor Receptors

K A Thomas, Drew University, Madison, NJ, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Angiogenesis Growth of new blood vessels from existing vessels.

Heparan sulfate proteoglycan (HSPG) A membrane or extracellular matrix-anchored sulfated glycoprotein.

Lymphangiogenesis Growth of new lymphatic vessels.

sVEGFR Alternatively spliced soluble vascular endothelial growth factor receptor (VEGFR) missing its transmembrane sequence and intracellular tyrosine kinase.

Vasculogenesis Embryonic *de novo* organization of blood vessels.

Vascular endothelial growth factor (VEGF) An extracellular soluble dimeric protein that binds and activates one or more VEGFRs.

VEGFR Full-length membrane-spanning VEGF receptor containing an intracellular tyrosine kinase.

Vascular Endothelial Growth Factor Receptor Genes

Evolution

The three vascular endothelial growth factor receptors (VEGFRs) are denoted VEGFR-1, VEGFR-2, and VEGFR-3, or Flt-1, KDR/Flk-1, and Flt-4, respectively. Each VEGFR gene encodes a protein composed of seven extracellular immunoglobulin (Ig)-like domains, a short transmembrane-spanning polypeptide, and an intracellular portion containing tyrosine kinase enzymatic activity. The VEGFRs are most closely related to the hematopoietic receptor tyrosine kinases c-kit, c-fms and Flt3, and to the platelet-derived growth factor receptor (PDGFR)- α and - β , each of which contains five extracellular Ig-like domains and an intracellular tyrosine kinase. The VEGFR-1, -2 and -3 genes are clustered with the hematopoietic receptors and PDGFRs on chromosomes 13, 4, and 5, respectively, consistent with divergence from a common ancestral receptor tyrosine kinase gene.

Structure

Each of the three VEGFRs is encoded by 30 exons. The corresponding exon-coding regions in each gene are of similar size although some of the introns that separate them vary substantially in length resulting in total genomic DNAs ranging from ~190 kb for VEGFR-1 to 47 kb and 46 kb for VEGFR-2 and -3, respectively. In all three genes, exon 1 encodes the secretory leader sequence, exons 2–15 span the extracellular region, exon 16 corresponds to the transmembrane-spanning polypeptide, and exons 17–30 encode the cytoplasmic region including the tyrosine kinase containing a kinase-insert-domain encoded by exon 21.

Gene Expression

Cellular differentiation status and responses to extracellular signals influence the expression of each of the VEGFR genes. Multiple transcription-factor-DNA-binding site consensus sequences are present within approximately the first 1 kb 5' of

the translational start site. Control regions within the first intron might also either augment or inhibit transcription.

VEGFR-1

Subsets of vascular endothelial cells, monocytes, dendritic cell precursors, glial cells, and smooth muscle cells express VEGFR-1. The basal promoter and 5' sequences that control VEGFR-1 endothelial cell-selective expression contain Ets, Sp1, Egr-1, and CRE transcription-factor-binding site consensus sequences, several of which have been shown to be functional. In addition, a single hypoxic response element is located within the first 1 kb 5' of the transcriptional start site, consistent with the observation that the transcription of VEGFR-1 is increased by hypoxia. Transcription is initiated downstream of a TATA box basal transcription-factor-binding site to generate a 7.5–8 kb messenger RNA (mRNA).

VEGFR-2

VEGFR-2 is expressed primarily by vascular endothelial cells although a few other cell types including subsets of neurons and their precursors can also express this receptor. Endothelial cell expression has been mapped to a region within the first 150 bp 5' of the transcriptional start site that contains multiple Sp1, Ap-2, and NF- κ B sites. *In vivo* expression of the corresponding murine VEGFR-2 gene has been studied using transgenic mice. Blood-vessel targeted gene expression in developing mouse embryos is controlled by sequences not only in the region 5' of the translational start site but also within the first intron. The human gene, which does not contain a TATA box, is transcribed as a 7-kb mRNA.

VEGFR-3

VEGFR-3 is expressed on lymphatic endothelial cells and the tips of growing capillaries. Several consensus transcription factor sequences have been recognized in the VEGFR-3 gene 5' of the translational initiation site and a 1.6-kb 5' region has been

reported to drive lymphatic expression. Full-length VEGFR-3 mRNA is transcribed as a 5.8-kb mRNA.

Protein Structure

The primary translation products of human VEGFR-1, -2, and -3 genes are 1338, 1356, and 1363 amino acid residue proteins, respectively, each containing a short N-terminal secretory leader sequence that is removed during posttranslational processing. The ~150-kDa protein is glycosylated at multiple sites on the extracellular sequence to generate mature proteins of 185–230 kDa. Partial proteolysis of VEGFR-3 generates an amino-terminal 70-kDa polypeptide disulfide linked to the remaining 120–125-kDa transmembrane protein.

Extracellular Domains

On the basis of sequence homology, the extracellular regions are predicted to be composed of seven Ig-like folding domains, denoted D1–D7 in the amino to carboxyl terminal direction. Crystal structures of the VEGFR-2 D2 and D3 domains complexed with VEGF-C (Figure 1), the isolated D7 domain, and the D2 domain of VEGFR-1 bound either to VEGF-A or to PlGF confirm their Ig-like folding patterns. These β -sandwich Ig-like domains are each composed of two antiparallel β -sheets enclosing a hydrophobic core containing a buried disulfide bridge.

Figure 1 Structure of the complex between a VEGF-C dimer and domains D2 and D3 of two VEGFR-2 receptor fragments. The antiparallel VEGF-A subunits are gold and green and the VEGFR-2 domains are light blue with disulfide bonds and carbohydrate chains shown in yellow and purple, respectively. The amino (N) and carboxyl (C) terminal ends of each subunit are labeled and the secondary structures are illustrated as arrows pointing toward the C-terminal ends. Reproduced from Leppänen V-M, Prota AE, Jeltsch M, et al. (2010) Structural determinants of growth factor binding and specificity by VEGF receptor 2. *Proceedings of the National Academy of Sciences of the United States of America* 107: 2425–2430, with permission from National Academy of Sciences.

Transmembrane and Intracellular Domains

Single-pass membrane-spanning sequences in each of the VEGFRs consist of short, approximately 22–25-amino-acid hydrophobic sequences. This is followed by a juxtamembrane domain, a two-domain tyrosine kinase and a C-terminal polypeptide sequence. The structure of the VEGFR-2 tyrosine kinase, shown in Figure 2, contains N- and C-terminal domains consisting primarily of β -strands and α -helices, respectively. The catalytic site is located at the interface of these two domains denoted by the adenosine diphosphate (ADP) modeled into the structure. It is flanked by the disordered activation-binding loop, the glycine-rich nucleotide-binding loop, and the catalytic loop that can participate in enzyme activation and substrate binding. The VEGFRs each contain a 65–70-amino-acid residue kinase-insert domain within the N-terminal region of the C-terminal kinase domain, which is deleted in the crystallized VEGFR-2 kinase. A C-terminally truncated form of VEGFR-3, missing 65 amino residues, is generated by alternative splicing.

Ligand Binding

VEGF Structure and Receptor Binding

The mammalian VEGF ligands are a family of five homologous dimeric glycoproteins, denoted VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor (PlGF). In addition, heterodimers containing VEGF-A and PlGF have been identified. Several functional VEGF homologs are either expressed by

Figure 2 Structure of the VEGFR-2 tyrosine kinase. The N- and C-terminal lobes are blue and red, respectively. The active site region between these two domains is denoted by the location of ADP modeled into it. The glycine-rich, catalytic, and activation loop disordered ends are shown in yellow. The ends of the largely deleted kinase-insert domain are also shown and labeled. Reproduced from Harada S and Thomas KA (2002) Vascular endothelial growth factors. In: Bilezikian JP, Raisz LG, and Rodan GA (eds.) *Principles of Bone Biology*, 2nd edn. vol. 2, pp. 883–902. San Diego, CA: Academic Press, with permission from Academic Press/Elsevier.

viruses or present in snake venoms, collectively denoted VEGF-E and VEGF-F, respectively. Diversity exists among these viral and snake venom VEGFs; some only bind VEGFR-2 whereas others also bind VEGFR-1. The crystal structures of VEGF-A, VEGF-B, VEGF-C, and PlGF homodimers show each ~120-amino-acid monomer to contain a central solvent-exposed antiparallel four-stranded β sheet with a cystine knot motif at one end composed of three intrachain disulfide bonds and one cysteine that forms an interchain disulfide bond with a cysteine at the opposite end of the adjacent antiparallel monomer. As shown in Figure 1, an N-terminal helix extends from the cystine knot end of each subunit and lies over the opposite end of the other subunit to form a small hydrophobic core.

Homodimeric VEGF ligands bind with pM affinity to one or more of the receptor homodimers as shown in Figure 3, in which dashed lines denote proteolytic removal of N- and C-terminal sequences of VEGF-C and -D required for increased affinity to VEGFR-2. Ligand binding promotes receptor dimerization. As seen in Figure 1, each of the two ligand dimeric subunits participate in binding to each of the receptor monomers. The loops between β -strands of both VEGF-C subunits interact with not only the D2 but also the D3 domain of each VEGFR-2 subunit. Similarly, the crystal structures of homodimeric VEGF-A and PlGF complexed at each end to the D2 domain of VEGFR-1 also show that this receptor domain simultaneously binds both ligand subunits. Additional stabilization might be conferred by weaker interactions between the two membrane-proximal D7 and probably the central D4 Ig-like domains in some or all of the VEGFRs, as illustrated in Figure 4. However, D7 interactions are not required for ligand-mediated receptor dimerization, consistent with observed formation of sVEGFR dimers.

Co-receptors

VEGF-A, VEGF-B, and PlGF are subject to alternative splicing that can incorporate C-terminal polycationic regions. These

Figure 3 Receptor–ligand binding selectivity. Normal tissue homodimeric VEGFs are listed in the top row and viral VEGF-Es and snake venom VEGF-Fs are present in the bottom row with color-coded arrows pointing toward the high-affinity VEGFRs that they bind. Dashed arrows from VEGF-C and -D to VEGFR-2 indicate high-affinity binding following proteolytic processing to remove N- and C-terminal polypeptides. Some viral VEGF-Es and snake venom VEGF-Fs bind only VEGFR-2, whereas others also bind VEGFR-1.

positively charged sequences promote binding to negatively charged soluble heparin and heparan sulfate proteoglycans (HSPGs) anchored to cellular membranes, extracellular matrix, and basement membranes. Although HSPGs do not induce VEGF signal transduction, they might promote VEGF activity by partitioning the ligands to cellular surfaces thereby increasing their local concentration in the vicinity of the high affinity receptors and by binding both the ligand and receptor. The VEGF/VEGFR complex may also associate with the cell-surface membrane-anchored proteins neuropilin-1, expressed in arteries, and neuropilin-2 found in venous and lymphatic vessels. Neuropilins appear to simultaneously bind the last few amino acid residues of the C-terminal tail of VEGF and heparan sulfate, which also binds the heparin-binding domain of VEGFs and VEGFRs allowing the formation of a VEGF/VEGFR/HSPG/neuropilin complex.

Signal Transduction

Receptor Tyrosine Kinase Activation

Receptor dimerization is necessary but not sufficient for the initiation of signaling. Formation of a pair of salt bridges between the receptor membrane-proximal D7 domains of a dimerized receptor is also required for transphosphorylation of each intracellular VEGFR tyrosine kinase by its dimeric partner as shown schematically in Figure 4. Interactions between adjacent D7 domains and perhaps the membrane-spanning sequences within receptor dimers presumably facilitate proper proximity and orientation of the intracellular tyrosine kinase domains required for mutual transphosphorylation. The initial transphosphorylation of tyrosine residues 1054 and 1059 on the tyrosine kinase activation loop of VEGFR-2 decreases the K_M of the enzyme for adenosine triphosphate (ATP) and for peptide substrates without altering K_{cat} , the effective maximal rate of enzyme activity. This increased affinity for substrates could reflect the movement of the phosphorylated activation loop to provide better substrate access to their binding sites. Activation loop tyrosines exist on VEGFR-1 and -3, so might function in a similar manner. Once activated, several other VEGFR tyrosine residues become phosphorylated. VEGF-induced receptor tyrosine phosphorylation is rapid, reaching maximal levels by 2–5 min, followed within 30 min by receptor internalization.

Activation of VEGF receptors can be inhibited by secreted soluble forms of VEGFR-1 (sVEGFR-1 or sFlt-1) and VEGFR-2 (sVEGFR-2), each of which consists of the six N-terminal Ig-like domains, as illustrated in Figure 4, and are generated by alternatively splicing. These soluble receptors can sequester or ‘trap’ VEGF ligands in a dimeric soluble receptor complex so they are not available to bind full-length transmembrane VEGFRs. In addition, they may dimerize with full-length membrane-spanning VEGFRs, thereby preventing receptor kinase transphosphorylation and activation thus acting in a dominant negative manner.

Recruitment of Signaling Proteins

Once the receptor tyrosine kinase enzyme is activated, additional tyrosines in the intracellular juxtamembrane region, the

Figure 4 VEGFR activation and inhibition by sVEGFR. The structures of VEGFRs contain seven extracellular Ig-like domains, a juxtamembrane region, the two-domain core tyrosine kinase and kinase insert domain, and a C-terminal tail (labeled on the left). Binding of dimeric VEGF to Ig-like domains 2 and 3 induces receptor dimerization, which can be aided by interactions between receptor domains 7 and probably 4 (shown in the upper right). This promotes phosphorylation of two kinase activation loop tyrosines, denoted by the red P labels, and enzymatic activation in VEGFR-2 and probably in VEGFR-1 and -3. Additional tyrosines in the juxtamembrane region, kinase-insert loop, and C-terminal tail are phosphorylated and bind signaling proteins that trigger several VEGF functions. The sVEGFRs can inhibit VEGFR activation by sequestering ligand and by forming dominant negative dimeric complexes with the full-length membrane-spanning receptors (lower right).

kinase insert domain, and the C-terminal tail can be phosphorylated, as shown schematically in Figure 4. Which subsets of tyrosines are phosphorylated on a particular VEGFR subunit can be influenced by whether it is in a homodimeric or heterodimeric receptor complex, which, in turn, influences the spectrum of downstream signaling events and biologic responses that are initiated. Phosphorylated receptor tyrosine residues can serve as recognition sequences for binding one or more signal transduction proteins including phospholipase $C\gamma$ ($PLC\gamma$) and several adapter proteins such as Grb2, Nck, Crk, Sck, Shc, Shb, and Vrap/TSAd that can bridge the receptors to signaling enzymes such as phosphatidylinositol 3-kinase (PI3K) and src.

Signal Transduction Cascades

Some of these phosphorylated tyrosine residues and their binding proteins have been linked to specific functions, including proliferation, migration, cell survival, and vascular permeability. For example, phosphorylation of VEGFR-2 Tyr₁₁₇₅ in the C-terminal tail is required for the efficient binding of $PLC\gamma$. The phosphorylation of VEGFR-2-associated $PLC\gamma$ activates its enzymatic activity catalyzing the hydrolysis of membrane-anchored phosphatidylinositol 4,5-bisphosphate to generate

inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). Water-soluble IP_3 activates an endoplasmic reticulum ion channel that releases Ca^{2+} , activating several enzymes including endothelial cell nitric oxide synthase, which promotes vascular permeability, and promoting the translocation of specific protein kinase C (PKC) isoforms to the membrane where they are activated by binding membrane-associated DAG. Activated PKC then activates the mitogen-activated protein kinase (MAPKK; also known as MEK), which, in turn, activates p42/44 MAPK that then enters the nucleus to modulate transcription. Additional pathways, mediated through PI3K, raf, src, and p38, activate cell migration, proliferation, survival, and vascular permeability.

Biologic Activities

Development

Each of the three VEGFRs are crucial for embryonic development as revealed by mouse homozygous gene knockouts that are each embryonically lethal. Blood vessels exist in VEGFR-1 knockout mice but are disorganized, which appears to be a consequence of modified hematopoietic cell fate leading to increased numbers of endothelial cell progenitor hemangioblasts that

alter vessel pattern formation. Surprisingly, knockout of the VEGFR-1 gene segment encoding the tyrosine kinase but retention of the extracellular and membrane-spanning regions leads to normal development of blood vessels and survival in approximately 50% of mice. This result is consistent with the possibility that one of the functions of VEGFR-1, which binds VEGF-A with ~10-fold higher affinity than VEGFR-2, might be to sequester low levels of VEGF, thereby buffering the VEGFR-2 receptor from inappropriate activation by low levels of VEGF. By contrast, the VEGFR-2 knockout is virtually devoid of vascular endothelial cells, consistent with its crucial role as a mediator of endothelial cell mitosis and survival. VEGFR-3 gene knockout mice exhibit vasculogenesis and angiogenesis in early developing embryos but large vessels appear abnormal with defective lumens leading to fluid accumulation in the pericardial cavity and cardiovascular failure. Therefore, at least during early embryogenesis, before lymphatic vessels develop from post-capillary venules, VEGFR-3 plays a crucial role in vascular development.

Neovascularization

In adults, activation of VEGFR-2 can mediate the survival, migration, and mitosis of vascular endothelial cells culminating in microvascular growth, termed 'angiogenesis'. Ligands such as VEGF-A and the viral VEGF-Es that bind VEGFR-2 are also sufficient to drive angiogenesis and the growth of hematopoietic progenitor cells. Antibodies to VEGFR-2 and enzyme inhibitors of the VEGFR-2 tyrosine kinase inhibit angiogenesis and the resulting growth of tumors in mice. VEGFR-3, which can form homodimers and heterodimers with VEGFR-2, is expressed in angiogenic sprouts and stimulation of VEGFR-3 can augment VEGF-induced angiogenesis, whereas VEGFR-3 antibodies suppress angiogenic sprouting and vascular network formation. By contrast, the VEGFR-1-selective ligand PlGF appears to promote the stabilization of existing microvessels by promoting pericyte coverage, maturation of precapillary arterioles by stimulation of smooth muscle cell growth, and development of larger collateral vessels, termed 'arteriogenesis', in both ischemic myocardium and limb muscles resulting in increased perfusion. Activation of VEGFR-1 by its selective ligands PlGF and VEGF-B can also induce vascular endothelial cell expression of proteins such as tissue factor, matrix metalloproteinases, urokinase, plasminogen activator inhibitor-1, hepatocyte growth factor, and pigment epithelium-derived factor that can modulate vascular growth.

The directional growth of new capillary sprouts is driven by VEGF-A gradients stabilized at least in part by binding to extracellular matrix components such as heparan proteoglycans. In addition, growing sprouts are guided away from the parental vessel by its local expression of sVEGFR-1, which can sequester VEGF-A forming an active angiogenic corridor perpendicular to the preexisting vessel, thus inhibiting formation of nonproductive microvascular loops back to the parental vessel. Natural expression of sVEGFR-1 in cornea is also necessary for the maintenance of corneal avascularity and clarity. Expression of transfected sVEGFR-1 by tumor cells severely inhibits their growth *in vivo* but not *in vitro*, consistent with an antiangiogenic mechanism. The VEGFR-2/VEGF-A system can promote tumor angiogenesis and growth and has been the focus of therapeutic anti-angiogenesis efforts. Bevacizumab, an

inhibitory monoclonal antibody that binds VEGF-A, has been approved for use as an adjunct to cancer chemotherapy.

Lymphangiogenesis

The lymphatic system, which develops during embryogenesis from the vascular venous system, drains excess extracellular fluids and transports antigen-presenting immune cells. VEGFR-3 is expressed by lymphatic endothelial cells and its activation supports their migration, proliferation, and survival. Consistent with these cellular activities, the VEGFR-3 ligands VEGF-C and -D can promote lymphangiogenesis, the growth of lymphatic capillaries. Homozygous gene knockouts of either VEGFR-3 or VEGF-C demonstrate that they are both required for the development of a functional lymphatic system. Naturally occurring human heterozygous VEGFR-3 missense mutations with inactive tyrosine kinases are linked to lymphedema, a genetic disease in which fluid accumulates in tissues as a consequence of deficient lymphatic function. Endogenous corneal expression of the naturally occurring soluble receptor sVEGFR-2 antagonizes VEGF-C and inhibits corneal lymphatic development, which prevents the trafficking of antigen-presenting cells and maintains immunologic privilege of the cornea *in vivo*. Therefore, the establishment of an optically clear and immunologically privileged cornea is achieved by endogenous expression of both sVEGFR-1 and sVEGFR-2. Surprisingly, sVEGFR-2 does not efficiently inhibit angiogenesis, which might indicate that it is functioning by formation of heterodimers with VEGFR-3. Heterodimerization of full-length VEGFR-2 and VEGFR-3 has been observed in lymphatic endothelial cells and results in phosphorylation of a different subset of receptor tyrosine phosphorylation sites compared to the corresponding homodimeric receptors. In animal models, VEGF-C and VEGF-D stimulate lymphatic metastasis and their expression in human tumors is correlated with cancer metastatic spread to lymph nodes and a poor clinical prognosis.

Nonmitogenic Functions

In adults, activation of VEGFR-2 induces hypotension and vascular permeability that can promote edema. By contrast, low circulating levels of the unbound VEGFR-2 ligands VEGF-A and PlGF and elevated levels of sVEGFR-1, which can sequester these ligands, is associated with preeclampsia, a condition manifest by hypertension and edema that occurs in 5–7% of pregnancies and causes increased fetal mortality. VEGF-A also promotes the synthesis of prostacyclin, a potent vasodilator and inhibitor of platelet aggregation, through formation of VEGFR-1/VEGFR-2 heterodimers but not the corresponding receptor homodimers.

The VEGFR system is also associated with inflammation. Activation of VEGFR-1 can induce the migration of monocytes and drive expression of monocyte and macrophage tissue factor, monocyte chemoattractant protein-1, and tumor necrosis factor- α . Inhibitory anti-VEGFR-1 antibodies suppress the mobilization of bone marrow myeloid progenitors into the circulation, the infiltration of leukocytes into inflamed tissues, and the resulting development of atherosclerotic and autoimmune arthritic lesions in mice.

All three VEGFRs have been found in the nervous system along with their ligands. In addition to their neurovascular

effects, the VEGF receptors and their ligands can promote neurogenesis, neuronal migration, neurite growth, and survival in a variety of cell culture and animal models. The VEGF/VEGFR system can also support the proliferation and function of a variety of glial cells including astrocytes, myelinating Schwann cells, and microglia.

Summary

The VEGFRs are composed of three homologous membrane-spanning tyrosine kinases that on ligand-induced dimerization not only mediate the development, growth, and function of blood and lymphatic vessels but also appear to be involved in certain aspects of the immune and nervous systems. Alternatively spliced inhibitory soluble receptors corresponding to two of the VEGFRs appear to provide endogenous specific inhibition of these activities. The inappropriate activation or inhibition of the VEGFRs and their ligands can have pathologic consequences making them targets for therapeutic intervention.

Vasopressin/Oxytocin Receptor Family

M J Brownstein, Azevan Pharmaceuticals, Bethlehem, PA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Baroreceptor Receptor in the walls of the heart or blood vessels that is stimulated by alterations in pressure.

Dieresis Increased urine excretion.

Diuretic An agent that increases urine excretion.

Hypothalamus The part of the brain that regulates the endocrine and autonomic and autonomic nervous systems, controlling water balance, blood pressure, body temperature, growth, and sexual function.

Lipogenesis Formation of body fat.

Magnocellular neurons Large neurons in the hypothalamus that manufacture vasopressin or oxytocin.

Natriuresis Sodium excretion in the urine.

Pressin An agent that increases blood pressure. In the context of this review, pressins are vasopressin-like peptides with nine amino acids, having a basic residue (arginine or lysine in the eighth position).

Tocin An agent that promotes childbirth by causing uterine contractions; an oxytocin-like peptide lacking arginine or lysine in the eighth position.

The Structures of Pressins and Tocins

For the last billion years, the peptides in vasopressin/oxytocin (VP/OT) family have retained certain structural features. With the exception of the hydrins (partially processed relatives of vasotocin, which are physiologically active in some amphibia) and Ci-VP (CFFRDCSNMDWYR, an unusual, divergent family member made by sea squirts), they all have nine amino acids and a C-terminal amide. Cysteine (C) is invariably present in positions 1 and 6, and the two cysteine residues form a cystine bridge, creating conformationally constrained, cyclic peptides. Except for Ci-VP and seritocin (serine5 and isoleucine8-OT), which was reported in a single species, *Bufo regularis*, all family members have asparagines (N) in position 5, and proline (P) and glycine (G) in positions 7 and 9, respectively. VP-like peptides (pressins) are characterized by the presence of arginine (R) or lysine (K) in position 8, while OT-like molecules (tocins) have leucine (L), isoleucine (I), glutamine (Q), valine (V), or threonine (T) there. All of the invertebrate peptides except for the locust diuretic hormone, which has not been detected in other insect species, have an R instead of Q, N, or S in position 4. Thus, the primordial peptide that gave rise to the molecules we know today should have looked rather similar to one of the conopressins or to vasotocin, the likely ancestor of all of the vertebrate hormones. (The molecules detected in *Hydra* with antivasopressin antibodies share the C-terminal PRG-amide motif with VP, but are otherwise unrelated.)

In addition to the peptides shown in Table 1 and Figure 1, it is worth noting that the major metabolite of VP (pGlu4 and cystine6-AVP) mobilizes calcium in some cells in the central nervous system, and has been suggested to have a unique, but as yet unidentified, receptor of its own.

Peptide Biosynthesis

The peptides in the VP/OT family are synthesized as parts of precursor proteins. The VP precursor has the following structural features:

signal peptide-CYFNQNCPRGG-K*R*neurophysin-copeptin

The signal peptide is removed cotranslationally in the endoplasmic reticulum, liberating the N terminus of the peptide. Then, after the precursor is packaged into vesicles by the Golgi apparatus, it is cleaved at the asterisked sites by a calcium-dependent Lys-Arg endoprotease. The remaining basic amino acids are removed by a carboxypeptidase B-like enzyme, leaving a glycine (G) on the carboxy terminus. This glycine serves as the donor of the amide group, which is generated by the sequential actions of a peptidyl-glycine monooxygenase and a peptidyl-hydroxyglycine lyase. Neurophysin is thought to serve as an internal chaperone, promoting proper folding and cystine-bridge formation. Copeptin, a glycosylated species, is part of the VP, but not the OT precursor. Its function is unknown, but since it is produced and released along with VP, its levels in the blood reflect those of the peptide, and it is a convenient biomarker for VP secretion. The genes encoding the VP and OT precursors are adjacent to one another on the same chromosome. In mammals, they are oriented tail to tail, and share regulatory elements. The gene elements responsible for cell-specific expression of the two peptides remain to be determined.

The Functions of VP and OT

VP/OT-like peptides play different roles in the various species where they are found. They are very commonly involved in water homeostasis and/or reproductive function. In humans, VP is an antidiuretic hormone. It is released from the posterior pituitary into the blood stream when the osmolarity (solute content) of the blood increases, and it acts on V2 receptors in the kidney to cause water retention. V2 receptors are Gs-coupled and increase intracellular cyclic AMP. This, in turn, causes preformed aquaporin (AQP) 2 channels to be inserted into the luminal surfaces of cells in the collecting ducts of the kidney. Water enters these channels, traverses the cells, exits through AQP 3 and 4 channels on their interstitial faces, and enters the bloodstream. Mutations in the genes encoding VP, the V2 receptor, or AQP2 cause diabetes insipidus – an inability to concentrate urine, resulting in high urine volumes and a

Table 1 Vasopressin, oxytocin, and related peptides

<i>Oxytocin-like peptides (tocins)</i>		
Oxytocin (OT)	CYIQNCPLG-amide	Mammals, Pacific ratfish
Mesotocin (MT)	CYIQNCPIG-amide	Nonmammalian tetrapods, marsupials, lungfish
[Phe2]Mesotocin (FMT)	CFIQNCPIG-amide	Australian lungfish
Seritocin (ST)	CYIQSCPIG-amide	Dryness-resistant African toad
Isotocin (IT)	CYISNCPIG-amide	Bony fish
Aspartocin (AspT)	CYINNCPLG-amide	Spiny dogfish
Asvatocin (AsvT)	CYINNCPLG-amide	Spotted dogfish
Glumitocin (GT)	CYISNCPLG-amide	Rays
Phasvatocin (PhT)	CYFNCPVG-amide	Spotted dogfish
Valitocin (ValT)	CYIQNCPLG-amide	Spiny dogfish
Annetocin (AnT)	CFVRNCPTG-amide	Earthworm
Cephalotocin (CT)	CYFRNCPIG-amide	Octopus
<i>Vasopressin-like peptides (pressins)</i>		
A-Vasopressin (AVP)	CYFQNCPRG-amide	Most mammals
L-Vasopressin (LVP)	CYFQNCPLG-amide	Pig, marsupials
Phenylpressin (PP)	CYFQNCPRG-amide	Marsupials
Vasotocin (VT)	CYIQNCPRG-amide	Non-mammalian vertebrates
Hydrin 2 (H2)	CYIQNCPLG	Frogs, toads
A-conopressin (ACP)	CIIRNCPLG-amide	Snail
L-conopressin (LCP)	CFIRNCPLG-amide	Snail, sea hare, leech
Locust diuretic hormone (LDH)	CLITNCPLG-amide	Locust (but not fruitfly), Red flour beetle, Jewel wasp
<i>Putative ancestor</i>	<i>C(F/Y)I(Q/R)NCP(R/K)G-amide</i>	

Abbreviations: C (cysteine), F (phenylalanine), G (glycine), I (isoleucine), K (lysine), N (asparagine), P (proline), Q (glutamine), R (arginine), S (serine), T (threonine).

need to consume large amounts of fluid each day. Since the V2 receptor gene is on the X chromosome, female carriers pass X-linked nephrogenic diabetes insipidus along to their sons, but not their daughters.

Nonosmotic as well as osmotic stimuli can trigger VP secretion. Osmoreceptors on cells in the anterior hypothalamus, and baroreceptors in the left ventricle of the heart, aortic arch, and carotid sinus monitor osmolality and blood pressure, respectively, and participate in controlling the firing of VP-producing cells during phenomena like hemorrhage.

In addition to V2 receptors, VP acts on V1a and V1b receptors. The former are found on blood vessels and are responsible for VP's pressor (blood pressure increasing) activity. In fact, VP and terlipressin, a V1a specific agonist, are used to treat catecholamine-resistant vasodilatory shock. Since certain vascular beds are especially sensitive to VP, including those in the skin and uterus, it has also been suggested that V1a receptor antagonists might be useful for treating vasospasm in Raynaud's disease and dysmenorrhea (menstrual cramps) which may result from excessive constriction of vessels in the digits and uterus, respectively.

V1b receptors are found on corticotrophs (adrenocorticotrophic hormone (ACTH) or ACTH-producing cells) in

Figure 1 Evolution of vasopressin-related (pressin) and oxytocin-related (tocin) peptides. The timescale (millions of years ago) was taken from Hedges (2002). Note that invertebrates and jawless fish make a single pressin or tocin per species, and that vertebrates make two or, in the case of marsupials, three such peptides – one or two pressins and one tocin. It appears that vasotocin was the ancestor of the vertebrate hormones, and it continued to be synthesized by all vertebrates except mammals, in which it was replaced by arginine or lysine vasopressin. It is not clear why cartilaginous fish make so many different tocins; lungfish make MT or FMT, and all of the remaining bony fish make IT. Based on the structures of the peptide precursors, it has been argued that lungfish are related to tetrapods (e.g., toads) and that bony fish form a separate lineage. Amphibians, lizards, birds, and marsupials make MT; egg-laying and placental mammals differ in the hormones they produce. Marsupials appear to have branched away as suggested by other analyses. It is worth noting that the receptors for the various pressins and tocins shown in this figure evolved in parallel with them. The abbreviations used in this figure are defined in Table 1.

the anterior pituitary. In addition to being made by magnocellular neurons, VP is also synthesized by small cells in the paraventricular nucleus of the hypothalamus. These same cells also make corticotropin-releasing hormone (CRH), and their axons terminate on portal vessels in the external zone of the median eminence. VP and CRH are released into these vessels and transported to the anterior pituitary, where they act in concert to stimulate ACTH secretion. ACTH, in turn, causes the adrenal to release glucocorticoids. Thus, VP is important in mediating the body's response to stress.

V1a and V1b, but not V2, receptors are found in the brain, and the central effects of VP agonists and antagonists are mediated by these receptors. These effects vary from species to species, and learning their roles in humans should be facilitated by the recent development of specific agonists and antagonists that can be used for imaging and clinical studies/trials. It appears that VP may mediate behavioral reactions to stress, aggressive and affiliative behavior, juvenile recognition, and parenting in rodents – especially males. In addition, V1a antagonists appear to block the vomiting associated with motion sickness in pigs and ferrets.

OT-producing mammals make a single receptor for this peptide. Like the V1a and V1b receptors, it is Gq-coupled, and activates phospholipase C (PLC), increasing intracellular calcium. The VSSV/I sequence, which is unique to V1a, V1b, and OT receptors, may participate in PCL coupling.

OT receptors increase dramatically in the pregnant uterus as term approaches. Despite the fact that it has been used for decades to induce uterine contractions, studies of knockout animals have shown that OT is not essential for parturition. This may explain why OT receptor antagonists are not always effective in treating preterm labor, especially when there is an intrauterine infection present. There is no doubt, however, that the pulsatile release of OT from the pituitary in response to cervical dilation and vaginal stimulation facilitates the expulsion of the fetus.

OT is required for milk ejection. Mechanical stimulation of pressure-sensitive receptors in the nipple of the breast by the nursing infant results in activation of magnocellular neurons in the hypothalamus and release of pulses of OT into the bloodstream. The hormone causes breast myoepithelial cells to contract, increasing intramammary pressure and forcing milk into the ducts. In the absence of OT, milk cannot be let down, and the infant will starve if it is not provided an alternative source of food.

In addition to its roles in parturition and lactation, OT appears to affect maternal and social behaviors. Based on the latter, its use in autism is being explored. In addition, it stimulates lipogenesis to compensate for lipid loss in the milk (via an action on insulin secretion) and may participate in regulating salt and water balance. While OT causes natriuresis in rats, it is not clear that this is the case in humans.

VP and OT Receptors

As expected from the fact that their ligands are similar, VP and OT receptors are structurally related. They are members of the rhodopsin superfamily, and have seven α -helical membrane-spanning domains connected to one another by intracellular and extracellular loops. The N terminus of each receptor faces the outside of the cell; the C terminus is cytoplasmic. The intracellular loops and C-terminal tail of the receptors interact with trimeric G proteins, coupling agonist binding to activation of second messenger systems. More than 40 VP/OT receptors found in species ranging from snails to humans have been cloned and sequenced. The primary sequences of some of these are shown in [Figure 2](#). It is remarkable that from the beginning of its first transmembrane domain (TM1) to the end of its seventh one (TM7), the snail conopressin receptor 2 is

43% identical in amino acid sequence to the human V1a, V1b, and OT receptors and the white sucker fish vasotocin receptor. Unlike the vertebrate proteins, however, the conopressin receptor responds equally well to lysine8- and isoleucine8-conopressin (an OT-like synthetic analog of lysine-conopressin). Duplication of a relatively promiscuous receptor of this sort might have permitted trial-and-error evolution of functionally distinct pressors and tocins in vertebrates.

A number of amino acids are conserved among all of the receptors in [Figure 2](#). Some of these residues are found in most G-protein-coupled receptors (GPCRs). Among them, the arginine (R2) in the DRY motif, found just beneath TM3, is thought to dwell in a pocket formed by polar residues in TMs 1, 2, and 7 when the receptor is in its inactive state. Hormone binding dislodges this arginine from its polar pocket, exposing G-protein docking sites on the cytoplasmic loops.

The cysteines in extracellular loops 1 and 2 (C1 and C2, respectively) are also highly conserved among rhodopsin-like receptors. They form a cystine bridge that links these loops, stabilizing the conformation of the receptors. The pair of cysteines (C3 and its neighbor) located 15 aa's below TM7 in the cytoplasmic tails of most VP/OT receptors are palmitoylated, and this is thought to anchor their C termini to the plasma membrane and play a role (in the case of the V2 receptor) in beta-arrestin binding, which leads to efficient receptor endocytosis and ERK1/ERK2 activation. Like other members of the rhodopsin superfamily, VP and OT receptors appear to be glycosylated on their N termini and regulated by phosphorylation of their intracellular domains.

A number of attempts have been made to model the binding of VP, OT, and vasotocin to their receptors. The models are fundamentally similar in the sense that they all predict that the peptide hormones fill a cleft located in the upper third of the barrel formed by the seven membrane-spanning α -helices. The hydrophobic amino acids that comprise the cyclic portion of the peptides (cysteine1, tyrosine2, isoleucine or phenylalanine3, and cysteine6) appear to reside in a hydrophobic pocket formed by aromatic residues on helices 3, 5, 6, and 7. The more polar amino acids (glutamine4 and asparagine5), and the amidated C terminus of the hormones occupy a hydrophilic region formed by residues on helices 2, 3, and 4. More specifically, residues that are conserved in the N-terminal domain and TMs 2, 3, 4, and 6 in most, if not all, of the VP/OT receptors (labeled R1, Q1, Q2, K, Q3, Q4, and Q5 in [Figure 2](#)) have been shown to be important for high-affinity binding, even though their predicted interactions with specific amino acids in the peptide hormones vary from model to model. Parsimony dictates that residues conserved among the various VP/OT peptides should interact with conserved domains in the receptors, but perhaps things are not this simple.

One amino acid appears to be crucial for peptide agonist selectivity. This residue (marked with a V in [Figure 2](#)) is found in the first extracellular loop, and it interacts with the eighth amino acid of the peptide hormones (arginine and leucine in AVP and OT, respectively). The aspartic acid or tyrosine residues found at V in the human V2 and V1a/V1b receptors, respectively, are responsible for their marked preferences for AVP versus OT. The phenylalanine in this position in the OT receptor accounts for its modest preference for OT over AVP.

Figure 2 Alignment of vasopressin and oxytocin receptors and selected relatives. To save space, the extracellular N termini and intracellular C termini have been removed. They are quite divergent, but it is remarkable that the transmembrane domains (TMs), the first two extracellular loops (linking TMs 2 and 3, and TMs 4 and 5), and portions of intracellular loops 2 and 3 (linking TMs 3 and 4, and TMs 5 and 6), have remained so similar throughout the course of their evolution. Specific residues in these domains are responsible for ligand binding and selectivity (see text), and other motifs are important for signal transduction. The variable intracellular portions of the receptors allow them to interact with specific G proteins.

VP and OT antagonist-binding sites appear to be different from the ones where the peptide hormones bind, but to overlap them partially. Recently, a peptide (CRAVKY) derived from the sequence of the second extracellular loop of the V2 receptor has been shown to act as a pharmacologically permissive, noncompetitive antagonist. It is an allosteric modulator of receptor function and exhibits functional selectivity – that is, it blocks VP-driven PGI₂ production and cremasteric vasorelaxation, but not camp production or beta-arrestin recruitment. Agents like this that affect one, but not all, second messenger systems triggered by GPCRs may have improved safety or specificity compared with more promiscuous antagonists.

Glossary

Access channel An aqueous channel that allows protons to reach buried carboxyl groups in the center of the membrane from one side of the membrane or the other.

Osteopetrosis A genetic disease in humans associated with the inability to degrade bone, one cause of which is a defect in the vacuolar proton translocating adenosine triphosphatase (V-ATPase) of osteoclasts.

Receptor-mediated endocytosis The process by which cells take up specific ligands from their environment (such as low-density lipoprotein) via cell-surface receptors.

V-ATPase Vacuolar proton translocating ATPase that carries out active proton transport from the cytoplasmic to the noncytoplasmic side of the membrane driven by energy released upon hydrolysis of adenosine triphosphate (ATP).

Vacuolar (H⁺)-Adenosine Triphosphatase Function

Function of Intracellular Vacuolar (H⁺)-ATPases

Vacuolar (H⁺)-adenosine triphosphatase (ATPases) (V-ATPases) have been identified in many intracellular compartments, including endosomes, lysosomes, Golgi-derived vesicles, and secretory vesicles. V-ATPases within endosomal compartments are important for the process of receptor-mediated endocytosis (Figure 1). During receptor-mediated endocytosis, cells take up ligands (such as the cholesterol-carrying complex, low-density lipoprotein, or LDL) from their environment by binding them to receptors on the cell surface and clustering these receptors in specialized regions of the plasma membrane (clathrin-coated pits) which then invaginate into the cell. Following this internalization, the ligand–receptor complexes are exposed to a low pH within the early (sorting) endosome that causes the internalized ligand to dissociate from its receptor. This dissociation allows the receptor to recycle to the plasma membrane (where it is reutilized) and the ligand to proceed to the lysosome, where it is degraded. The low pH within the endosome is generated by the V-ATPase.

Acidification of endosomes is also important in the formation of carrier vesicles that carry the released ligands from early to late endosomal compartments and in the delivery of newly synthesized lysosomal enzymes from the Golgi to lysosomes. The latter process involves the binding of these enzymes to mannose-6-phosphate receptors in the *trans*-Golgi followed by their delivery to an endosomal compartment. Within this compartment, the low pH created by the V-ATPases causes dissociation of the lysosomal enzymes from their receptors, allowing delivery of the enzymes to the lysosome and recycling of the receptors to the *trans*-Golgi. Finally, endosomal acidification is involved in the entry of certain envelope viruses (such as influenza virus) and toxins (such as diphtheria and anthrax toxins) into cells. These viruses and toxins bind to the surface of cells and are internalized by the process of endocytosis. Upon exposure to a low pH, the virus coat fuses with the endosomal membrane, releasing the viral nucleic acid into the cytoplasm of the host cell. In the case of internalized toxins, the low pH induces a conformational change in a portion of the

toxin which creates a pore in the endosomal membrane through which the cytotoxic portion of the toxin enters the cell. Endosomal acidification is, therefore, essential in the process by which these viruses and toxins infect and kill cells.

Lysosomes are the major compartment in which degradation of proteins and other macromolecules occurs in cells. The lysosomal enzymes responsible for this degradation all require an acidic environment to be active. This acidic environment is created by the V-ATPases. Secretory vesicles, such as synaptic vesicles, are also acidic compartments. Synaptic vesicles are located at the synaptic terminal of nerve cells and release neurotransmitters (that chemically trigger the next nerve cell) by fusion with the plasma membrane. Neurotransmitters become concentrated within synaptic vesicles by transport proteins within the synaptic vesicle membrane that utilize either the proton gradient or the membrane potential generated by the V-ATPases to drive uptake of the transmitter. Finally, beyond their role in acidification, V-ATPases have been suggested to play a direct role in membrane fusion.

Function of Plasma Membrane V-ATPases

Plasma membrane V-ATPases play an important role in a number of normal and disease processes. In alpha-intercalated cells in the kidney, V-ATPases are located in the apical membrane where they pump protons into the urine, thus helping to control the pH of the blood. A genetic defect in this pump leads to a disease called renal tubule acidosis, in which the kidney is unable to secrete sufficient acid. V-ATPases are also present in the plasma membrane of osteoclasts, which are cells that function in degradation of bone. These cells are essential during development to facilitate bone remodeling. Plasma membrane V-ATPases in osteoclasts create an acidic extracellular environment that is necessary for bone degradation to occur. A genetic defect in the V-ATPase in osteoclasts leads to the human disease autosomal recessive osteopetrosis, in which the inability to degrade bone leads to severe skeletal defects and perturbations in Ca²⁺ homeostasis.

Plasma membrane V-ATPases in macrophages and neutrophils have been shown to help maintain a neutral internal

Figure 1 Function of intracellular V-ATPases. Acidification of early (sorting) endosomes by the V-ATPase facilitates receptor recycling following endocytic uptake and formation of endosomal carrier vesicles. Recycling M6P receptors to the *trans*-Golgi is also dependent on a low luminal pH. V-ATPase activity is required to drive neurotransmitter uptake by secretory vesicles and facilitates protein degradation in lysosomes. Finally, endosomal acidification facilitates the entry of the cytotoxic portions of viruses (such as influenza virus) and toxins (such as diphtheria toxin) into cells (see text).

pH under conditions of severe acid load. In the vas deferens, V-ATPases create a low pH environment necessary for sperm development. V-ATPases in the plasma membrane of tumor cells have also been proposed to function in tumor invasion by providing an acidic extracellular environment necessary for secreted lysosomal enzymes to degrade extracellular matrix. There is, thus, interest in V-ATPase inhibitors as potential anticancer drugs. Finally, V-ATPases in intestinal cells in insects create a membrane potential across the apical membrane that is used to drive potassium transport into the gut.

V-ATPase Structure

The V-ATPase is a large complex composed of 14 different subunits. These subunits are arranged into two separate domains termed V_1 and V_0 (Figure 2). The V_1 domain is made up entirely of subunits that are peripheral to the membrane (i.e., not membrane embedded). This domain has a molecular mass of ~720 kDa and contains eight different subunits (subunits A–H) of molecular mass 70–13 kDa (Table 1). The V_1 domain is responsible for hydrolysis of ATP, which occurs on catalytic sites located on the three copies of subunit A. There are, therefore, three catalytic nucleotide-binding sites per complex. The B subunits (which are also present in three copies per

complex) can also bind nucleotides, but these sites are referred to as ‘noncatalytic’ sites, since they do not actually hydrolyze ATP. The function of these sites is not known, but they may play a role in controlling the activity of the V-ATPase. The A and B subunits are arranged in a hexamer, like the segments of an orange, with alternating A and B subunits. ATP is hydrolyzed sequentially at each of the three catalytic sites. The other subunits in the V_1 domain (subunits C–H) function to connect the V_1 domain to the V_0 domain and are discussed here.

The V_0 domain in yeast is composed of six different subunits (subunits a, d, c, c', c'', and e) of molecular mass 100–9 kDa. All of the subunits in the V_0 domain except subunit d are embedded in the membrane and, thus, require detergent for solubilization. The V_0 complex has a molecular mass of 260 kDa and is responsible for transport of protons across the membrane. This proton transport only occurs when the V_1 domain is attached to V_0 and is driven by the hydrolysis of ATP in V_1 . Three of the subunits in the V_0 domain are called ‘proteolipid subunits’ (c, c', and c'') because they are so hydrophobic that they can be extracted from the membrane using organic solvent mixtures, such as chloroform:methanol. These subunits are almost completely embedded in the membrane and the polypeptide chain of each one crosses the membrane 4–5 times (these are called ‘transmembrane segments’). Buried in the middle of one of the transmembrane segments of each of

Figure 2 Structure of the V-ATPases. The V-ATPases contain two domains. The V_1 domain is responsible for ATP hydrolysis and the V_0 domain carries out proton transport across the membrane. Like the F-ATPases, the V-ATPases operate by a rotary mechanism in which ATP hydrolysis in V_1 drives rotation of a central stalk which is connected to a ring of proteolipid subunits in V_0 . It is movement of the proteolipid ring relative to subunit a that drives proton transport (see text). An Arginine (Arg) residue on subunit a and glutamic acid (Glu) residues on the ring of proteolipid subunits are crucial for proton translocation and are shown in red and green, respectively. Charged residues on subunit a that contribute to proton-conducting hemi-channels are shown in yellow.

Table 1 Subunit composition of the V-ATPase

Domain	Subunit	Gene (yeast)	M_r (kDa)	Function/location
V_1	A	<i>VMA1</i>	69	Catalytic ATP-binding site
	B	<i>VMA2</i>	58	Noncatalytic ATP-binding site
	C	<i>VMA5</i>	44	Peripheral stalk, regulation of reversible dissociation
	D	<i>VMA8</i>	29	Central stalk
	E	<i>VMA4</i>	26	Peripheral stalk
	F	<i>VMA7</i>	14	Central stalk
	G	<i>VMA10</i>	13	Peripheral stalk
	H	<i>VMA13</i>	54	Peripheral stalk, inhibition of free V_1 ATP hydrolysis
V_0	a	<i>VPH1/STV1</i>	100	Proton translocation, targeting
	d	<i>VMA6</i>	40	Cytoplasmic side
	c	<i>VMA3</i>	17	Proton translocation, bafilomycin-binding site
	c'	<i>VMA11</i>	17	Proton translocation
	c''	<i>VMA16</i>	23	Proton translocation
	e	<i>VMA9</i>	9	Unknown

the proteolipid subunits is a single essential glutamic acid residue, which is reversibly protonated and deprotonated during proton transport by the V-ATPases. Like the A and B subunits in the V_1 domain, the proteolipid subunits in the V_0

domain form a ring, with four copies of subunit c and one copy each of subunit c' and c''. The specific V-ATPase inhibitor bafilomycin has been shown to bind to the proteolipid subunits of the V_0 domain.

In addition to the proteolipid subunits, the a and e subunits of V_0 are also embedded in the membrane. Subunit a is 100 kDa and is made up of two domains. The carboxyl-terminal half of the molecule contains eight transmembrane segments while the amino-terminal half is a hydrophilic domain that is present on the cytoplasmic side of the membrane. Like the proteolipid subunits, subunit a also contains amino acid residues that are essential for proton transport. In particular, there is a positively charged arginine residue near the middle of the seventh transmembrane segment of subunit a that is absolutely required for proton transport by the V-ATPases. Subunit e is a small (9 kDa) highly hydrophobic protein of unknown function. The function of subunit d, which is tightly bound to the V_0 domain but is not embedded in the membrane, is thought to be in bridging the central stalk of V_1 (see below) with the proteolipid ring of V_0 . It should be noted that in mammals there is no gene encoding subunit c', but that the mammalian V_0 domain contains an additional accessory subunit (Ac45) of unknown function.

The V_1 and V_0 domains are connected by a single central stalk and multiple peripheral stalks. The central stalk is composed of the subunits D and F, whereas the peripheral stalks are composed of subunits C, E, G, H, and the soluble domain of subunit a. The function of these stalks is described below.

Mechanism of ATP-Driven Proton Transport by the V-ATPases

The V-ATPases operate by a rotary mechanism, similar to that demonstrated for the F-ATPases (or ATP synthases), which are enzyme complexes present in mitochondria, chloroplasts, and bacteria that function in the reverse direction (that is in proton-driven ATP synthesis). For the V-ATPases, ATP hydrolysis in the V_1 domain drives rotation of the central stalk (containing subunits D and F), which in turn drives rotation of the ring of proteolipid subunits relative to subunit a in the V_0 domain. Subunit a is held fixed relative to the A_3B_3 hexamer of V_1 by the peripheral stalks (or stators), composed of subunits C, E, G, H, and the soluble domain of subunit a. Recent data indicate there are three peripheral stalks, each of which contain a heterodimer of subunits E and G. It is rotation of the ring of proteolipid subunits relative to subunit a that drives active transport of protons from the cytoplasmic to the luminal side of the membrane. A proton enters from the cytoplasmic side of the membrane via a cytoplasmic access channel in subunit a and protonates a buried carboxyl group on one of the proteolipid subunits. ATP hydrolysis in V_1 forces rotation of the proteolipid ring in the plane of the membrane such that the protonated carboxyl group on the proteolipid subunit reaches a second access channel in subunit a that leads to the luminal side of the membrane. Interaction between this carboxyl group on the proteolipid subunit and the buried arginine residue of subunit a (which is positively charged) forces the proton off of the proteolipid subunit into the luminal access channel, where it can be released to the luminal side of the membrane, thus completing the transport cycle. In this way, the rotary motion driven by hydrolysis of ATP is converted into unidirectional transport of protons across the membrane.

Regulation of V-ATPase Activity *In Vivo*

The activity of V-ATPases in different membranes in the cell is known to be regulated such that the pH of different intracellular compartments and the degree of proton transport across the plasma membrane are carefully controlled, but the mechanisms employed in regulating V-ATPase activity in cells are still being elucidated. One important mechanism of regulation involves reversible dissociation of the V-ATPase complex into its component V_1 and V_0 domains. In yeast, dissociation occurs in response to removal of glucose from the media, probably as a way to preserve cellular energy stores. This process has been shown to be regulated by the Ras/cAMP/protein kinase A pathway. Reversible dissociation has also been demonstrated to occur in insects and in mammalian cells. In dendritic cells, activation of antigen processing increases V-ATPase assembly on the lysosomal membrane as a way to stimulate antigen processing, which depends upon the activity of proteases that have optimal activity at low pH. A second proposed regulatory mechanism involves the formation of a disulfide bond between conserved cysteine residues located at the catalytic site on the subunit A. Differences in the efficiency of coupling of ATP hydrolysis and proton transport have also been observed for V-ATPases containing different isoforms of subunit a and likely help to explain the difference in pH of different intracellular compartments.

Changes in the density of V-ATPases in different cellular membranes have also been proposed as a means of controlling proton transport. This has been shown to occur in intercalated cells in the kidney, where exposure to a low pH causes the fusion of intracellular vesicles containing the V-ATPase with the plasma membrane, thus increasing proton transport out of the cell into the renal fluid. Regulated exocytosis of V-ATPases has also been demonstrated in epididymal clear cells. Differential targeting of V-ATPases to different cellular membranes appears to be controlled by isoforms of the a subunit. Thus, the a3 isoform is able to target the V-ATPase to the plasma membrane in osteoclasts, whereas the a4 isoform targets the V-ATPase to the intercalated cell plasma membrane. It is mutations in these isoforms that lead to the human diseases osteopetrosis and renal tubule acidosis mentioned earlier. Isoforms have now been identified in many of the V-ATPase subunits in mammalian cells, and these have been shown to be expressed in both tissue- and organelle-specific manner. This has led to the expectation that specific inhibitors can be identified that are selective in their ability to inhibit particular V-ATPase complexes, which may in turn lead to the development of drugs for the treatment of diseases such as osteoporosis and tumor metastasis.

Glossary

k_{cat}/K_m A measure of the efficiency of an enzyme for its substrate from dividing the rate of turnover of the substrate by the enzyme by the Michaelis constant.

K_d (equilibrium dissociation constant) A measure of the affinity of a protein for its ligand. Lower numbers indicate higher affinity.

Retinoid-binding protein Proteins that bind specific retinoids with high affinity, several of them with $K_d \leq 10$ nM.

Short-chain dehydrogenase/reductase (SDR) A gene family consisting of ~50 mammalian members in the range of 25–35 kDa that uses pyridine nucleotide cofactors to dehydrogenate or reduce steroids, retinoids, prostanoids, and intermediates in lipid metabolism.

Retinoids and Their Functions

The term retinoid refers to naturally occurring and synthetic compounds with vitamin A activity: the term vitamin A denotes the compound all-*trans*-retinol (atROH). All vertebrates require vitamin A for vision, fertility, embryogenesis, regulation of energy balance, and growth. atROH does not itself fulfill the physiological functions of vitamin A; rather it acts as precursor for biosynthesis of metabolites directly responsible for producing vitamin A activity. These atROH metabolites include 11-*cis*-retinal, the cofactor that covalently binds with opsin to form the visual pigment rhodopsin; all-*trans*-retinoic acid (atRA), the humoral effector of the nonvisual, systemic functions attributed to vitamin A; and 9-*cis*-RA (9cRA), a regulator of glucose-stimulated insulin secretion. These systemic functions include: controlling the differentiation programs of epithelia and of stem cells in the skin, nervous system, bone, immune system, hemopoietic system; acting as a tumor suppressor; regulating apoptosis; regulating energy balance, adiposity, and glucose/insulin tolerance. Nonvisual effects of retinoids also include memory formation, immune responsiveness, stress adaptation, cell fate determination, and suppression of carcinogenesis. atRA and 9cRA activate three nuclear receptors, retinoic acid receptor (RAR) α , β , and γ , and thereby control the expression of hundreds of genes. atRA also binds with PPAR δ/β . Both RAR and PPAR heterodimerize with RXR. CRABPII delivers atRA to RAR, whereas FABP5 delivers atRA to PPAR δ/β . atRA and 9cRA also function through nongenomic mechanisms.

The Chemistry of atROH Generation, Storage, and Metabolic Activation

Carotenoids with at least one β -ionone ring, especially β -carotene, provide the major retinoid precursors in most diets. Oxidative central cleavage by a plasma-membrane-associated, but soluble, carotene 15,15'-monooxygenase (CMO1) produces all-*trans*-retinal – a transient intermediate that occurs in very low concentrations outside of the neural retina. Microsomal retinal reductases (RRDs), members of the short-chain dehydrogenase/reductase (SDR) gene family, catalyze reduction of all-*trans*-retinal into atROH, which then

undergoes esterification with fatty acid moieties, predominantly palmitate, into all-*trans*-retinyl esters (atREs) by microsomal lecithin:retinol acyltransferase (LRAT). Chylomicra transport atRE into circulation and deliver some to adipose, whereas chylomicra remnants deliver most to liver, where ultimately most REs are stored in stellate cells.

In the visual cycle, atREs undergo concerted hydrolysis isomerization into 11-*cis*-retinol by RPE65-isomerohydrolase (IMH), followed by dehydrogenation into 11-*cis*-retinal by SDR. 11-*cis*-Retinal forms a Schiff's base with a lysine residue in the protein opsin to form rhodopsin. When light strikes the neural retina, 11-*cis*-retinal in rhodopsin undergoes *cis*- to *trans*-isomerization, causing a conformation change that initiates nerve impulses through activation of G-proteins, and releases the newly formed all-*trans*-retinal. Reduction of all-*trans*-retinal into atROH (by microsomal SDR) and re-esterification (by LRAT) into atRE completes the visual cycle.

Activation of atROH into atRA uses the same intermediate used in the visual cycle, all-*trans*-retinal, but relies on a metabolically distinct route. atROH, either from blood or from hydrolysis of retinyl esters by microsomal retinyl ester hydrolase (REH), undergoes reversible dehydrogenation into all-*trans*-retinal, catalyzed by microsomal retinol dehydrogenases (RDHs), members of the SDR gene family. In contrast to the comparatively high concentrations of retinal that allows the visual cycle to function, all-*trans*-retinal concentrations during atRA biosynthesis are kept low (50–200 nmol g⁻¹) by reduction (back-reaction of RDH and reduction by microsomal and peroxisomal reductases), and by irreversible dehydrogenation into atRA, catalyzed by soluble retinal dehydrogenases (Raldh), members of the aldehyde dehydrogenase (ALDH) gene family. atRA isomers occur *in vivo*, such as 13-*cis*-RA and 9,13-di-*cis*-RA, but their significance and source (s) remain unclear. Recently, the issue of physiological occurrence of 9cRA as a bona fide hormone has been resolved with its analytically rigorous identification in the pancreas, and the inability to detect it (<0.05 pmol g⁻¹) in a variety of other retinoid target tissues.

These straightforward reactions offer complex opportunities for physiological regulation, owing to compartmentalization, distinct enzymes catalyzing each direction of chemically reversible reactions (e.g., dehydrogenation/reduction of retinol/retinal; esterification/hydrolysis of atROH/atRE), cell-distinct expression patterns, and multiple homologs/paralogs that

Table 1 Physiologically important Rdh

Mouse	Rat	Human
Rdh1	Rdh2, Rdh2_rat, Rdh7 (Rodh2, Rodh1/3)	Rdh16 (RDH-E, RoDH4, NP_0036992)

catalyze several reactions. For example, at least four reductases have been identified, which belong to the SDR gene family, Rrd (peroxisomal) and Rdh10 outside of the eye, and retSDR and Rdh12, in the neural retina. At least three Rdh's (SDRs) have been identified in the rat, mouse, and human (Table 1). Four Rdh's have been identified in human, rat, and mouse: Rdh1, 2, 3, 4 (aka ALDH1A1, 1A2, 1A6, and 8A1). These constitute a complex enzyme system for absorbing and storing vitamin A, maintaining atRA homeostasis, and recycling vitamin A in the visual cycle.

Retinoid-Binding Proteins and Retinoid Homeostasis

Processing of dietary retinoids and retinoid precursors and biogenesis of active retinoids relies on serum and cellular chaperones for efficient and specific retinoid use, as demonstrated by studies *in vitro* and the consequences of gene knockouts and/or naturally occurring mutations.

Liver and other tissues synthesize a retinol-binding protein, RBP (aka Rbp4), a member of the lipocalin gene family. atROH egress from liver requires sRBP, and sRBP-atROH represents the major form of vitamin A in serum. sRBP circulates as a complex with a tetramer of transthyretin, which protects the ~20 kDa sRBP from kidney filtration. Recent work shows that some cells have a cell-surface receptor, Stra6, which recognizes sRBP. The sRBP-null mouse seems phenotypically normal when fed a diet that contains copious amounts of vitamin A, except for impaired vision after weaning. Feeding a diet with lower, but normally adequate amounts of vitamin A, prevents reproduction in the sRBP-null mouse. Although the eye relies on sRBP for efficient atROH uptake, atROH obtained from postprandial lipoprotein delivery can substitute if the animals are fed diets with copious amounts of vitamin A. Interestingly, atRA serum levels increase in the sRBP null mouse even during high vitamin A diets, indicating that serum delivery of atRA to tissues helps compensate for impaired atROH delivery.

Binding proteins channel retinoid intermediates through the series of reactions that constitute the visual cycle (Figure 1). Mice null in the retinal pigment protein RPE65-IMH, for example, cannot produce 11-*cis*-retinoids, consistent with an RPE65-IMH function of binding the hydrophobic atRE ($K_d \sim 20$ pM), and catalyze acyl hydrolysis and C11 isomerization. RPE65 belongs to the same gene family as the carotenoid-metabolizing enzyme CMO1 (the mouse proteins

have only 37% amino acid identity, however), suggesting a gene family devoted to transport/metabolism of hydrophobic substances. The RPE65-IMH product, 11-*cis*-retinol, undergoes sequestration in the RPE by the cytosolic cellular retinal-binding protein (CRALBP), a member of the gene family that includes the α -tocopherol transfer protein. CRALBP facilitates dehydrogenation of 11-*cis*-retinol into 11-*cis*-retinal, and drives forward the *trans*- to *cis*-isomerization. Mutations in human CRALBP cause night blindness and photoreceptor degeneration. RDH4 and RDH5, respectively, represent the murine and human 11-*cis*-retinol dehydrogenase, which interacts with and/or accepts substrate from CRALBP. Mutations in RDH5 are associated with the rare, autosomal recessive disease fundus albipunctatus, that is, night blindness from delayed photopigment regeneration. Lack of total blindness in the case of the RDH5 mutation indicates that SDRs in addition to RDH4/5 contribute to 11-*cis*-retinal biosynthesis, such as Rdh11. 11-*cis*-Retinal transverses the interphotoreceptor matrix by an unknown mechanism and covalently binds with opsin to form rhodopsin in the rod outer segment (ROS). After the action of light, an adenosine triphosphate (ATP)-dependent transporter, ABCR, facilitates release of all-*trans*-retinal from rhodopsin. Another SDR, Rdh12 (plus other SDRs) then reduce all-*trans*-retinal into atROH, which migrates back through the interphotoreceptor space to the RPE.

Outside of the vision cycle, several cellular retinoid-binding proteins (CRBPs) occur, other than those mentioned above with respect to the visual cycle. These include: CRBPI, CRBP II, CRBP III, CRABPI, and CRABPII (Table 2), which are ~15 kDa globular proteins of the intracellular lipid-binding protein (iLBP) gene family that includes the various fatty acid-binding proteins. All vertebrates express all five, with well-conserved amino acid sequences among orthologs. All are high affinity (except CRBP III), soluble, and specific for their ligands. CRBPI binds atROH, and closely related compounds such as 3,4-didehydro-atROH and all-*trans*-retinal to a lesser extent, and discriminates against atRA. CRABPI binds atRA, metabolites such as 4-OH-atRA, and discriminates against *cis*-RAs and atROH.

The cellular retinol/retinal-binding proteins enclose atROH and all-*trans*-retinal with the hydroxyl/aldehyde function, crucial to metabolic activation, sheltered inside. CRBPI and II confer selective advantage to vertebrates by enhancing efficiency of storing and transporting vitamin A, and limiting its catabolism. Vitamin A absorption and biosynthesis in the intestine relies on CRBP II. CRBP II null mice pups die within 24 h after birth, when delivered by dams fed a diet marginal in vitamin A content. CRBP II contributes ~1% of the soluble protein to the intestinal enterocyte – an indication of a mass-action function to sequester newly synthesized (from carotenoids) all-*trans*-retinal or newly absorbed dietary atROH. *In vitro*, all-*trans*-retinal bound with CRBP II undergoes reduction readily, but neither it nor bound atROH undergoes efficient dehydrogenation. This would limit production of atRA, and other metabolism, from the bolus of all-*trans*-retinal produced during carotenoid cleavage. In the intestine, the esterifying enzyme LRAT recognizes atROH bound with CRBP II to produce atRE for incorporation into chylomicra. Thus, CRBP II likely aids atROH uptake and chaperones the products of

Figure 1 Major paths of retinoid metabolism. The white background designates reactions of retinol homeostasis and activation into atRA in the liver and extrahepatic vitamin A target tissues. The light gray background depicts reactions that occur both in extraocular tissues and in the retinal pigment epithelium (RPE) of the neural retina. The yellow background designates reactions that occur in the RPE and in the rod outer segments (ROSs). Numbers indicate the positions of *trans*- to *cis*-isomerization (C11), the positions of hydroxylations that occur during catabolism of atRA (C4 and C18), and the positions of atRA isomers of physiological interest (C9, C13). The dotted lines indicate the direct actions of apo-CRBPI in regulating atRE hydrolysis and atROH esterification. The dashed-dotted line indicates transcriptional induction of cytochromes P-450 (CYP) by atRA. For simplicity, CRBPII and III are not shown. As these are intracellular reactions, sRBP and the plasma membrane sRBP receptor, Stra6, are not shown. The biosynthetic path of 9cRA is not certain, but SDRs can convert 9-*cis*-retinol into 9-*cis*-retinal, and Raldh can convert 9-*cis*-retinal into 9cRA *in vitro*.

Table 2 Major extraocular retinoid-binding proteins

Retinoid-binding protein	Ligand(s)	K_d (nM)	Postembryonic distribution
CRBPI (cellular retinol-binding protein, type I)	atROH, 9cROH	~10	Nearly ubiquitous (low in intestine)
CRBPII (cellular retinol-binding protein, type II)	all- <i>trans</i> -retinal	10–50	Intestine, neonatal liver
CRBPIII (cellular retinol-binding protein, type III)	atROH	10–50	Heart, muscle, adipose, mammary
CRABPI (cellular retinoic acid-binding protein, type I)	all- <i>trans</i> -retinal	~100	Widespread
CRABPII (cellular retinoic acid-binding protein, type II)	atRA	0.4	Limited (e.g., skin, uterus, and ovary)
	atRA	2	

carotenoid metabolism down the pathway to atRE to enhance efficiency of retinoid recovery from the diet.

Extra-intestinal vitamin A uptake and storage relies on CRBPI. CRBPI-null mice seem morphologically normal, but eliminate atRE sixfold faster than wild-type mice, and may sequester/esterify atROH less efficiently. CRBPI-null mice also have impaired glucose tolerance. Clearly, efficient use of atROH *in vivo* depends on this chaperone. Strikingly, CRBPI has a K_d value for atROH far lower than the atROH

concentration in tissues (0.2–30 μ M), and CRBPI concentrations exceed atROH concentrations, where measured. The law of mass action predicts from these data that nonesterified atROH would occur nearly exclusively bound with CRBPI, in the absence of alternative high-affinity or high-capacity acceptors. Nonspecific alternatives to CRBPI exert limited influence *in vivo*, because isolation of CRBPI from liver by traditional, time-consuming biochemical techniques produces largely holo-protein. Evidently, the capacity of membranes and other

potential acceptors to sequester atROH does not overwhelm the ability of CRBPI to sequester atROH. Like CRBP, LRAT can access atROH bound with CRBPI to produce atRE. Ultimately, liver stellate cells accumulate most of the atREs. CRBPI seems necessary for retinoid transfer from hepatocytes to stellate cells, because the CRBPI-null mouse does not accumulate atRE in stellate cells.

atROH sequestering within CRBPI, the need to store retinol as RE and the need for atRA biosynthesis during specific times at specific loci, suggests that transfer of atROH for metabolism might depend on relationships between metabolizing enzymes and CRBPI. Like CRBP, CRBPI allows esterification of bound atROH, but in contrast to CRBP, CRBPI also allows dehydrogenation of atROH. The CRBPI-atROH complex shows Michaelis-Menton relationships with atRE formation by LRAT and atROH dehydrogenation by RDH. This relationship with the microsomal RDH is maintained even with changes in the CRBP/atROH ratio (provided the CRBPI concentration exceeds the atROH concentration). This eliminates a free diffusion mechanism of transfer from the complex to select enzymes. Specific crosslinking of holo-CRBPI with both RDH and LRAT confirms close proximity of CRBPI and these two enzymes. In addition, a single mutation in an exterior residue of CRBP (L35A) reduces the V_m of atROH dehydrogenation by microsomes, but does not alter the K_m , or the K_d of atROH binding to CRBPI, consistent with conservation of exterior residues that aid transfer of atROH from CRBPI to enzymes. Obviously, atRE and atRA biosynthesis *in vivo* occurs in the absence of CRBPI, as indicated by the lack of morphological pathology in the CRBPI-null mouse, and their ability to sequester RE, albeit inefficiently. This was predicted by the experiments *in vitro*, which showed that neither RDH nor LRAT require presentation of atROH by CRBPI. Not surprisingly, the enzymes' active sites recognize their substrates in the absence of CRBPI. CRBPI operates as a chaperone, which restricts atROH metabolism to select enzymes, and seems required only for efficient atROH use *in vivo*. The ability of LRAT and RDH to access retinol from CRBPI addresses the issue of how atROH would undergo efficient metabolism in the face of limited diffusion from the binding protein.

Knockouts of *Rdh1* and *Rdh10* have phenotypes related to dysfunctions of retinoid-regulated genes and retinoid action. The *Rdh1*-null mouse is up to 11% longer and 37% heavier than wild type, and the *Rdh10*-null mouse dies during embryogenesis because of impaired brain development. Both have disturbances in retinoid metabolism.

RALDHs catalyze the irreversible conversion of atRCHO (all-*trans*-retinal) into atRA in the presence of CRBPI, and can also use atRCHO generated *in situ* from CRBPI-atROH and RDH, or in cells presented with atROH and transfected with RDH and RALDH. In the rat, RALDH1 and RALDH2 have differing, but overlapping, expression patterns, and respond differently to changes in atROH status. This suggests a purpose for multiple RALDH, that is, precise control over atROH use and atRA generation. The RALDH1-null mouse remains fertile and healthy, when fed a diet copious in vitamin A, but may have decreased ability to produce atRA in the liver, and seems to resist weight gain. The RALDH2-null mouse dies *in utero* at midgestation, demonstrating its unique contribution to atRA biosynthesis at a specific time embryogenesis. The situation

may differ in the adult, as testes express RALDH2 strongly, but RALDH1 prevails outside of the testis. The RALDH3-null mouse dies during suckling from an obstruction in the nose. Apparently, RALDH can compensate for each other after critical developmental milestones.

A CRBP^{III} has been detected in limited tissues – some express little or no CRBPI or CRBP^{II} – but has not been detected in other retinoid target tissues, such as liver, kidney, and brain. CRBP^{III} seems to bind about equally well with atROH, 9-*cis*-retinol and 13-*cis*-retinol, but with much lower affinity, either CRBP or CRBP^{II}. In adipose CRBP^{II} functions in lipid metabolism. Humans express yet another CRBP, originally referred to as CRBP^{III}, but distinct from mouse CRBP^{III}, and therefore CRBP^{IV}. CRBP^{IV} mRNA is much more abundant in human liver and intestine than CRBP^{II} mRNA, but the mouse does not encode a complete CRBP^{IV} gene. CRBP^{IV} binds atROH with a K_d value of ~ 60 nM, and does not bind *cis*-isomers. The precise functions of CRBP^{III} and CRBP^{IV} have not been clarified, and unlike CRBPI and CRABP, their endogenous ligands have not been established.

Knockouts of the atRA-binding proteins, CRABPI and CRABP^{II}, have not clarified their functions. Doubly null mice have a nearly fourfold higher rate of death from unknown causes by 6 weeks after birth than wild type, but the survivors appear normal, when fed a diet copious in vitamin A (chow diet), with one exception. The doubly null mouse as well as the CRABP^{II}-only null mouse show 83% and 45%, respectively, incidence of a small outgrowth anomaly on the postaxial side of digit 5, predominantly in the forelimbs. Mice doubly null in CRABPI and CRABP^{II} do not exhibit enhanced sensitivity to exogenous atRA, suggesting that the binding proteins do not protect against atRA toxicity. In contrast to CRBPI, both CRABPI and CRABP^{II} allow projection of the β -ionone ring of their ligand. Significantly, the first reactions of atRA degradation occur at these comparatively accessible sites, that is, C4 and C18. Presenting atRA to microsomes bound with CRABPI enhances kinetic efficiency (k_{cat}/K_m) of catabolism sevenfold. There seems to be little doubt that CRABPI sequesters atRA: delivering the sequestered atRA for efficient catabolism seems a logical mechanism to discharge the ligand without releasing it back into the cell. CRABPI tends to express in cells different from those that express CRBPI and CRABP^{II}, suggesting restriction of atRA function. CRABP^{II}, but not CRABPI, can deliver atRA to RAR in the nucleus, via a transfer that does not require free diffusion. This would complete the chaperoning of atROH on its journey from atRE hydrolysis to atRA biogenesis and nuclear localization.

Metabolism of Pharmacological Retinoid Concentrations

Many other enzymes, including medium-chain alcohol dehydrogenases (ADHs), and aldo-keto reductases, metabolize retinoids *in vitro*, which seems to confirm the need for evolution of CRBP to protect the sparse and valuable vitamin A from clearance as a xenobiotic. These enzymes do not access atROH bound with CRBP. The ADH1-null deer mouse, a natural mutant, and mice made null in ADH1, ADHIV, or ADHIII or doubly null in ADH1 and ADHIV do not: (1) present with

phenotypes resulting from inadequate vitamin A; (2) show compensatory responses in retinoid metabolism; (3) show changes in retinoid-regulated genes; and (4) have disrupted metabolism of physiological amounts of retinoids. Dosing toxic amounts of atROH (50 mg kg⁻¹ or ~300-fold higher than the recommended daily intake) to mice produces a serum atRA concentration ~1600-fold higher than normal. In the ADHI-null mouse, this is reduced to ~200-fold higher than normal. These data show that huge amounts of retinol can overwhelm physiological chaperones and provide a mechanism for retinol toxicity, as modest increases in atRA lead to retinoid toxicity.

Other Naturally Occurring Retinoids

Discrete loci, such as skin and the chick limb bud, synthesize 3,4-didehydro-atRA. 3,4-Didehydro-atRA binds RARs with affinity similar to that of atRA. The purpose of creating a signaling molecule that functions as atRA in specialized loci that also biosynthesize atRA has not been clarified, but subtle differences in ligand structure can have significant differences on the conformation of their receptors. These differences can lead to recruitment of different cofactors and/or binding of different response elements. This is illustrated by the development of synthetic retinoids that act as RAR agonist, antagonists, or inverse agonists. It is reasonable to infer that atRA and 3,4-didehydro-atRA regulate different genes, even though both bind RAR.

Although 9cRA was reported as a physiological ligand of RXR, it is undetectable *in vivo* in the vitamin A-target tissues assayed, except for pancreas. It, therefore, is unlikely to serve as a universal ligand for RXR, but it does modulate glucose-stimulated insulin secretion.

Control of Vitamin A Homeostasis

The primary regulators of retinoid homeostasis appear to be apo-CRBPI and atRA. apo-CRBPI inhibits LRAT and stimulates retinyl ester hydrolysis. Thus, the direction of flux into or out of atRE would reflect the ratio apo-CRBPI/olo-CRBPI, which would reflect the atROH status of the cell. atRA may serve as a signal to liver to release atROH into the serum. Little has been revealed about humoral regulation of atRA biosynthesis, but estrogen and prostaglandin E increase and decrease, respectively, atRA biosynthesis in cultured cells. The metabolism of atRA limits its activity; conversely, inhibitors of atRA metabolism enhance atRA potency. atRA induces its own oxidative metabolism into 5,6-epoxy-atRA, 18-hydroxy-atRA, and 4-hydroxy-atRA, through inducing cytochrome P-450s (CYPs). CYP26A1, B1, C1, and CYP2C39 (mouse only) appear to have major functions in the catalysis of atRA catabolism. CYP26A1-null mice die in mid- to late gestation with serious morphological defects. The precise function(s) of CYP26B1, 26C1, and 2C39 have not been clarified, but 26B1 and 2C39, like 26A1,

are induced by atRA. Many other CYPs reportedly catabolize atRA (e.g., CYP1A1/2, CYP2A6, CYP2C8/9, CYP2E1, and CYP3A4/5), but atRA does not induce these isoforms and most have inefficient kinetics with atRA *in vitro*.

It is notable that PPARδ/β, an atRA activated transcription factor, induces transcription of CMO1, CRBPI, CRBP2, LRAT, and RARβ, indicating regulation of vitamin A homeostasis by atRA, and suggesting correlation between vitamin A homeostasis and lipid metabolism.

Several xenobiotics, including ethanol and polychlorinated aromatic hydrocarbons, reduce atRE stores, likely through enhancing atRA catabolism by inducing CYP: the polychlorinated hydrocarbons, such as dioxin, function through the AH receptor to decrease atRE stores.

Clinical Uses of Retinoids

Numerous studies have correlated vitamin A insufficiency in laboratory animals with increased incidence of spontaneous and carcinogen-induced cancer. Chemopreventive trials in humans show some promise for retinoids in actinic keratoses, oral premalignant lesions, laryngeal leukoplakia, and cervical dysplasia. The FDA has approved retinoids for acute promyelocytic leukemia and in non-life-threatening diseases such as cystic acne and psoriasis. Retinoids also provide the active ingredients in agents to treat sun/age damaged skin, through regulating transcription, differentiation, and cell function in the skin.

The WHO recognizes vitamin A deficiency as a mortality factor for childhood measles. Two large doses (60 000 REQ each) of a water-soluble vitamin A formulation given to children on each of 2 days decrease the risk of death from measles 81% in areas of prevalent vitamin A deficiency.

Glossary

Adequate intake (AI) One of the four terms used to define dietary reference intakes (DRIs), which are reference values that are quantitative estimates of nutrient intakes to be used for planning and assessing diets for healthy people. The AI is used when the RDA for a nutrient is not available. It is an RDI that is based on observed or experimentally determined approximations of nutrient intake by a group of healthy people.

Amidation A complex reaction, which in some hormones results in a C-terminal protein modification. A C-terminus consensus sequence is required. The consensus is glycine, followed by two basic amino acids (Arg or Lys). The end product is an amide of glycine ($-\text{NH}-\text{CH}_2-\text{CO}-\text{NH}_2$) with loss of the basic amino acid residues.

Anthocyanins Naturally occurring compounds that impart color to fruits, vegetables, and plants. They also have antioxidant and insecticidal properties.

Carnitine Essential component of fatty acid transport into and out of mitochondria for their eventual oxidation. Carnitine is derived from the amino acid lysine following extensive modification.

Complement A term originally used to refer to the heat labile factor in serum that causes immune cytolysis, the lysis of antibody-coated cells. The term now refers to the entire functionally related system comprising at least 20 distinct serum proteins that is the effector immune cytolysis and other biologic functions immune system-related functions.

Dioxygenase An oxidoreductase that incorporates two atoms of oxygen (from one molecule of O_2) into the (reduced) substrate.

Fenton reaction The formation of $\text{OH}^\bullet$, OH^- , and Fe^{3+} from the nonenzymatic reaction of Fe^{2+} with H_2O_2 .

Gibberellins Plant hormones that stimulate growth in the stem and leaves, and trigger the germination of the seed.

Mehler reaction Describes the photoreduction of oxygen in chloroplasts by photosystem I in plants yielding $\text{O}_2^{\bullet-}$.

Monoxygenase Oxidoreductases that induce the incorporation of one atom of oxygen from O_2 into the substance being oxidized.

Recommended dietary allowance (RDA) The average daily dietary intake level that is sufficient to meet the nutrient requirement of nearly all (97–98%) healthy individuals in a group.

Redox Oxidation–reduction reaction in which electrons are removed from one molecule or atom and given to another molecule or atom.

Transporter A class of transmembrane protein that allows substances to cross plasma membranes far faster than would be possible by diffusion alone. A major class of transport proteins that expend energy to move substances (called active transport) are the transport ATPases.

Violaxanthin Photopigment involved in photoprotection in plants. When light energy absorbed by plants becomes excessive (relative to the capacity of photosynthesis), the xanthophyll (a chemical classification designation), violaxanthin is reversibly modified by violaxanthin de-epoxidase as a protective function in plants.

Ascorbic acid (vitamin C) is one of the most important redox cofactors in plant and animal systems. Although most animals make sufficient ascorbic acid; for some, ascorbic acid is a true vitamin because of an inability to carry out sufficient synthesis or production. This is true for humans and other higher primates, a small number of other mammals (e.g., guinea pigs and bats), and some species of birds and some fish. A deficiency causes the disease scurvy in humans, which results in a range of pathologic symptoms, because of defects in ascorbic-acid-specific enzymatic steps and processes. Scurvy in its most severe stages impacts collagen-related supporting structures and can lead to skin lesions and bleeding from the mucous membranes. In advanced scurvy, suppurating wounds, loss of teeth, and psychological changes may occur. Scurvy was first described by Hippocrates (c. 460 BC–c. 380 BC). A Scottish surgeon in the British Royal Navy, James Lind, was among the first to recognize scurvy as a nutritional disease. In early literature, scurvy is sometimes referred to as Barlow's disease,

Moeller's disease, and Cheadle's disease. Ascorbic acid was isolated in 1933 and synthesized in 1934.

Ascorbate synthesis occurs as a glycogenolysis-dependent process. In most plants and animals, ascorbic acid is derived as a product from the direct oxidation of glucose, galactose, and mannose (in plants). Steps in the reaction are glucose or galactose $\rightarrow$ UDP-D-glucuronic acid $\rightarrow$ glucuronic acid/glucuronolactone $\rightarrow$ gulono-1,4-lactone $\rightarrow$ ascorbic acid. In animals, a key enzyme in this process is L-gulonolactone oxidase (GLO, EC 1.1.3.8), which catalyzes the terminal step in ascorbic acid synthesis, that is, gulono-1,4-lactone is oxidized to ascorbic acid. In keeping with the evolutionary links to glucose metabolism, L-gulonolactone oxidase resides in the kidney of most birds and reptiles, and during the course of evolution was transferred to the liver of mammals. In animals that produce insufficient ascorbic acid, mutations in the L-gulonolactone oxidase gene occurred 50–60 million years ago in animals that produce insufficient ascorbic acid. Accordingly, a dietary source of ascorbic

acid is needed in these animals. There is a possibility that minor alternative pathways exist for ascorbic acid synthesis.

Chemistry

The chemical designation for ascorbic acid is 2-oxo-L-theohexono-4-lactone-2,3-enediol. Ascorbic acid is a near planar five-member ring with two chiral centers that resolves into the four stereoisomers. It has a molecular mass of $176.12 \text{ g mol}^{-1}$, a density of 1.65 g cm^{-3} , is very soluble in water ($>30 \text{ g per 100 ml}$), and variably soluble in most short-chain alcohols and glycols ($1\text{--}5 \text{ g per 100 ml}$). The oxidized form of ascorbic acid, dehydroascorbic acid, retains vitamin C activity and can exist as a hydrated hemi-ketal. Crystalline dehydro-L-ascorbic acid can exist as a dimer. The most important chemical property of ascorbic acid is the reversible oxidation of ascorbic acid to semidehydro-L-ascorbic acid and to dehydroascorbic acid (Figure 1).

In addition to facilitating reduction-oxidation reactions, ascorbic acid has the ability to form relatively stable free radical intermediates. Ascorbic acid can act as a free radical scavenger in reactions involving reactive oxidant species (ROS). In this regard, the rate constants for the generation of ascorbate radicals vary considerably, but often dictate rapid radical formation (e.g., $10^5 - 10^{10} k_{\text{obs}}$, unit $\text{M}^{-1}\text{s}^{-1}$). Once formed, ascorbate (Asc) radicals decay relatively slowly by a process of disproportionation ($2 \text{ Asc}^{\bullet-} + \text{H}^+ \rightarrow \text{AscH}^- + \text{DHA}$). The ability to form free radical intermediates can significantly delay or prevent free radical-initiated oxidations. Ascorbic acid readily scavenges reactive oxygen and nitrogen species, such as superoxide, hydroperoxyl, peroxynitrite, and nitroxide radicals. $\text{Asc}[\text{H}^{\bullet-}]$ donates a hydrogen atom ($\text{H}^{\bullet}$ or $\text{H}^+ + \text{e}^-$) to an oxidizing radical to produce the resonance-stabilized tricarbonyl ascorbate free radical. $\text{Asc}[\text{H}^{\bullet}]$ has a pK_a of -0.86 ; thus, it is not protonated. Further, the unpaired electron of $\text{Asc}[-]$ resides in the π -system that includes the tricarbonyl moiety of

ascorbate. It is a weakly oxidizing and reducing radical. Due to its π -character, $\text{Asc}[-]$ does not react with oxygen to form peroxy radicals capable of damaging oxidations. It is relatively unreactive with a one-electron reduction potential of only $+282 \text{ MV}$, and as such is considered a terminal, small-molecule antioxidant.

Ascorbic acid is often associated with the protection of lipid, DNA, and proteins from oxidants. As examples, when peroxy radicals are generated in plasma, vitamin C is consumed faster than other antioxidants (e.g., uric acid, bilirubins, and vitamin E). Ascorbic acid is 10^3 times more reactive than a polyunsaturated fatty acid in reacting with peroxy radicals. In contrast, ascorbic acid can be viewed as a pro-oxidant under aerobic condition when metals capable of redox ($\text{Fe}^{2+} \leftrightarrow \text{Fe}^{3+}$; $\text{Cu}^+ \leftrightarrow \text{Cu}^{2+}$) are also present. Metals, such as iron and copper in their reduced states, are effective Fenton catalysts.

With regard to other chemical properties, the acidity of ascorbic acid is due to the low pK_a of the proton on oxygen-3. In addition, ascorbic acid is not very stable in aqueous media, wherein it can decay within a few hours or even minutes at high pH (>10.0). By contrast, ascorbic acid is relatively stable in blood (a day or more), or if stored at acid pH (<3.0) or below -20°C (often weeks to months).

Nutritional and Biochemical Importance

Ascorbic acid functions in many mono- and dioxygenases to maintain metals in a reduced state. For example, mono- and dioxygenases usually contain copper or iron as redox cofactors, respectively. As an additional characteristic, dioxygenases require α -ketoglutarate and O_2 as cosubstrates in reactions, while mono-oxygenases require only O_2 . Important reactions and processes that require ascorbic acid include:

- Norepinephrine synthesis – dopamine- β -hydroxylase, EC 1.14.17.1, is the final and rate-limiting step in the synthesis

Figure 1 Chemical forms of ascorbic acid, major metabolites and degradation products.

of norepinephrine and requires copper and ascorbic acid for activity.

- Hormone activation – posttranslational steps involving α -amidations activate many hormones and hormone-releasing factors. Examples of hormone activation include melanotropins, calcitonin, releasing factors for growth hormone, corticotrophin and thyrotropin, pro-ACTH, vasopressin, oxytocin, cholecystokinin, and gastrin. Petidylglycine α -amidating mono-oxygenase (EC 1.14.17.3), the enzyme that carries out α -amidation, is found in secretory granules of neuroendocrine cells.
- Carnitine biosynthesis – ascorbate is a cofactor for two of the hydroxylation steps in the pathway of carnitine biosynthesis, gamma-butyrobetaine hydroxylase, and epsilon-N-trimethyllysine hydroxylase. Ascorbate deficiency results in as much as 50% decrease in carnitine in heart and skeletal muscle in animals that require ascorbic acid.
- Prolyl and lysyl hydroxylations – ascorbic acid is an important cofactor in the hydroxylation of proline and lysine amino acid residues. In scurvy, poor wound healing, bruising, and osteopenic abnormalities can result from the under-hydroxylation of collagens. The various types of collagens are distinguished by their relative amounts of hydroxyproline and hydroxylysine. Hydroxylation of proline and lysine is important in collagen assembly and maturation into fibers. Because collagen is the principal connective tissue protein in the body, it is essential to all phases of normal growth, development, and repair. There are also other proteins that are not defined as collagens, which contain hydroxyproline, for example, the subcomponent C1q of complement, acetylcholine esterase, pulmonary surfactant proteins, and proteins that function as cell-surface receptors. In plants, prolyl hydroxylase hydroxylates proline residues in cell wall hydroxyproline-rich glycoproteins required for cell division and expansion. Approximately, 50 hydroxyproline-containing proteins have been identified in viruses and bacteria, wherein ascorbic acid may also play a role as cofactor.

Ascorbic acid, along with glutathione, is an important non-enzymatic antioxidant/reductant in the water-soluble compartment of cells. Glutathione is L- γ -glutamyl-L-cysteine-glycine (GSH). The antioxidant actions of glutathione and ascorbate are closely linked and involve mechanisms in which decreased glutathione may even stimulate ascorbic acid synthesis in those animals that can produce it. During postnatal development, a rapid change occurs as animals adapt from a relatively hypoxic to a relatively hyperoxic environment. In this regard, one of glutathione's many functions is to keep ascorbic acid in a reduced form. An adequate ascorbic acid intake is particularly important in newborns and neonates, who do not yet have the potential to synthesize ascorbate. In adult animals that can make ascorbic acid, a reduction in glutathione levels can lead to a rapid increase in liver dehydroascorbic acid. A deficiency of both ascorbic acid and glutathione can cause pathologic changes to liver and other organs.

The mechanisms for ascorbic acid regeneration are complex. Both nonenzymatic and enzymatic processes have been proposed. In plants, dehydroascorbate reductase (DHAR) catalyzes the regeneration of ascorbic acid from its oxidized state and serves as an important regulator of Asc recycling,

particularly in plants. In animal cells, DHAR is also recognized as the intrinsic activity of thioltransferases (glutaredoxins) and protein disulfide isomerase. These enzymes catalyze the glutathione-dependent two-electron regeneration of ascorbic acid. Their importance is observed in studies of GSH-deficient rodents. GSH deficiency in newborn animals resulted in decreased tissue ascorbic acid and increased dehydroascorbate-to-ascorbate ratios. Administration of ascorbic acid daily to GSH-deficient animals decreased animal mortality and cell damage from oxygen stress. In this regard, a cellular role is proposed for dehydroascorbate in the oxidation of nascent protein dithiols to disulfides catalyzed in the endoplasmic reticulum compartment by protein disulfide isomerase. In chromaffin vesicles and neurohypophyseal secretory vesicles, semidehydroascorbate can be reduced by cytochrome b_{561} to regenerate intravesicular ascorbate. Cytochrome b_{561} , a transmembrane protein, is reduced in turn by an extravesicular electron donor, most probably cytosolic GSH or ascorbic acid. In the erythrocytes of some mammals, cytochrome b_{561} can also reduce extracellular monodehydroascorbate by using intracellular ascorbate (Asc) as an electron donor.

In plant tissues, ascorbic acid reaches a concentration of over 20 mM in chloroplasts and occurs in all cell compartments, including the cell wall. It has a major role in photosynthesis, acting in the Mehler peroxidase reaction with ascorbate peroxidase to regulate the redox state of photosynthetic electron carriers and as a cofactor for violaxanthin de-epoxidase, an enzyme involved in xanthophyll cycle-mediated photoprotection. Ascorbic acid also serves as a cofactor in metabolic pathways important to ethylene, gibberellins, and anthocyanins. There is a rapid response of ascorbate peroxidase expression to (photo)-oxidative stress. Of interest, the ascorbate-deficient vtc 1 mutant of *Arabidopsis thaliana* is very sensitive to ozone, ultraviolet-B radiation, and other forms of oxidant stress.

Cellular Regulation of Ascorbic Acid

Specific nonoverlapping transport proteins mediate the transport of ascorbic acid across biological membranes. In animals, dehydroascorbic acid uptake occurs by the facilitated-diffusion glucose transporters (GLUT1, -3, and -4), but under physiological conditions these transporters do not appear to play a major role in the uptake of dehydroascorbic acid due to the high concentrations of glucose that effectively block influx. In contrast, L-ascorbic acid enters cells via Na^+ -dependent systems. Two isoforms of these transporters have recently been cloned from human and rat sources, which differ in their tissue distribution. Sodium-ascorbate co-transporters (SVCT)1 and SVCT2 import reduced ascorbate across plasma membrane. SVCT2 is involved in vitamin C transport in almost every tissue, except red blood cells which lose SVCT proteins during maturation. Cell accumulation of ascorbic acid occurs, because of cellular dehydroascorbate reduction systems, noted above, that are capable of rapidly generating ascorbic acid. In addition to cell regulation, ascorbate reduction systems are also important in reducing the ascorbic acid radical. As indicated, the ascorbic acid radical is relatively stable. An accessory enzymatic system is needed to reduce the potential of transient accumulation of the ascorbate radical. Excess ascorbate radicals may

initiate free radical cascade reaction or nonspecific oxidations. In plants, nicotinamide adenine dinucleotide (NADH)-monodehydroascorbate reductase (EC 1.6.5.4) has evolved to maintain ascorbic acid in its reduced form. NADH-monodehydroascorbate reductase plays a major role in stress-related responses in plants. In animal tissues, glutathione dehydroascorbate reductase (EC 1.8.5.1) serves this purpose.

Digestion, Absorption, and Nutritional Requirements

When ascorbic acid is consumed in the diet, the ileum and jejunum are major sites of ascorbic acid absorption. The bioavailability of vitamin C is dose dependent. In humans, saturation of transport occurs with dosages of 200–400 mg d⁻¹. Approximately, 70% of a 500 mg dose is absorbed. However, much of the absorbed dose (>50%) is not metabolized and excreted in the urine. With a dose of 1250 mg, only 50% of the dose absorbed and most (>85%) of the absorbed dose is excreted. Vitamin C is not protein bound and is eliminated with an elimination half-life of 10–12 h. In Western populations' plasma, vitamin C concentrations range from 54 to 91 μmol l⁻¹. Some tissues can accumulate as much as 100 times the level of ascorbic acid in blood (e.g., adrenal glands, pituitary, thymus, corpus luteum, and retina). Tissue concentrations range from micromolar to millimolar amounts, that is, high tissue levels of vitamin C are tolerated in mammalian systems. However, there is also evidence that accelerated metabolism or disposal of ascorbic acid occurs after prolonged supplementation of high doses of ascorbic acid, that is, ascorbic acid levels in tissues are maintained by metabolically controlled or regulated processes.

Sources and Detection

A number of approaches are available for ascorbic acid detection. The most common approach involves titration with oxidizing agents. Ascorbic acid absorbs strongly in UV light, the basis for some spectrophotometric assays. The redox properties of ascorbic acid allow for electrochemical detection or detection from interacting with redox-sensitive chromophores and dyes. Enzymatic methods (using ascorbate oxidase) and isotope ratio mass spectrometry are also used for detection and quantitation of ascorbic acid following separation by ion exchange, absorption, or partition chromatographic approaches. Typical food and tissue values are given in Table 1.

Defining Ascorbic Acid Status

Most mammals that require ascorbic acid meet their requirements at intakes of 20–80 mg per 1000 kcal (4.184 MJ). This amount corresponds to what may be extrapolated from synthetic rates in animals that produce ascorbic acid. Such calculations, however, require knowledge of the amount of glucose directed through the direct oxidative pathway and eventually to L-glulonolactone oxidase, allometric scaling approaches, and diurnal fluxes in L-glulonolactone oxidase activity. Regrettably, this is seldom done, which can lead to errors, such as suggesting theoretical intakes of gram quantities of ascorbic acid per day for humans.

Table 1 Vitamin C in selected foods and tissues

<i>Sources of vitamin C</i>	<i>Mg of ascorbic acid per 100 g of wet weight or edible portion</i>
<i>Animal products</i>	
Cow's milk	0.5–2
Human milk	3–6
Beef, pork, veal	2–10
Beef, pork Liver	20–30
Liver, chicken	15–20
Oysters (raw)	30
Kidney, chicken	6–8
Heart, chicken	5

Horseradish	50
Lettuce, various	10–30
Leek	15
Parsley	200–300
Pepper, various	150–200

The requirements for vitamin C in humans (given as the range for female–male and expressed as the recommended dietary allowance (RDA) or adequate uptake (AI)) are as follows: infants, 40 mg d⁻¹ (AI based on what is present in

human milk); children (3–13 years), 15–45 mg d⁻¹ (extrapolated from the RDA for adults); adolescence, 45–65 mg d⁻¹; adults (>19 years), 75–90 mg d⁻¹; lactating mothers, 115–120 mg d⁻¹. In keeping with these estimates, recent clinical investigations have noted vitamin C deficiency in 2–7% of individuals surveyed (often defined as individuals meeting less than two-thirds of the RDA). A serum concentration of 11.4 mmol l⁻¹ is indicative of a vitamin C deficiency and clinical symptoms of scurvy. With regard to marginal vitamin C status based on plasma ascorbic acid values (e.g., <20–28 µg dl⁻¹), the prevalence ranges from 13% to 22% in the US population. Individuals who smoke are more likely to have marginal vitamin C status compared to nonsmokers. Several studies suggest that smokers require over 200 mg vitamin C daily in order to maintain plasma vitamin C concentrations at a level equivalent to that of nonsmokers. Genetic variations in transporters or enzymes involved in ascorbate metabolism can also affect functions or steady-state concentration of the vitamin. Consequently, there is potential for individuals with gene differences to have higher requirements for vitamin C. This is an area for future research.

Summary

Ascorbic acid usually carries out redox reactions by mechanisms dependent upon free-radical processes. Ascorbate metabolism is linked to the metabolism of glutathione. Ascorbic acid is required in animals that lack or have mutations in the gene for L-gulonolactone oxidase. Ascorbic deficiency results in reduced mono- and dioxygenase activities. The consequences of severe deficiency are profound, since growth, extracellular matrix, and hormonal regulation are impaired. Recent data suggest that optimal intakes of ascorbic acid, based on a range of criteria, should be 75–90 mg d⁻¹ for adult humans, and possibly higher in some circumstances.

Glossary

Coactivator A protein that participates with transcription factors to enhance receptor activity in transcription.

Convulsive tetany A disease precipitated by either low blood calcium or low blood magnesium, resulting in a severe convulsive state. It is lethal unless immediately treated with calcium and/or magnesium.

Corepressor A protein that participates with transcription factors to decrease target gene expression.

7-Dehydrocholesterol An intermediate in cholesterol biosynthesis and precursor of vitamin D₃.

Dovonex® A drug marketed by Leo Pharmaceutical containing an analog of 1,25-(OH)₂D₃ and used to treat psoriasis by topical administration.

Ergosterol A plant-derived sterol that is converted to vitamin D₂ upon ultraviolet irradiation.

Hepatocytes Cells comprising approximately 30% of the liver that carry out many of the liver's functions.

Keratinocytes Cells of the skin that produce the keratin proteins and contribute to the skin barrier.

Macrophage A type of white blood cell from the myeloid cell lines that is responsible for engulfing and destroying foreign materials.

Nongenomic Activities that are carried out not involving gene expression.

Osteoblasts Cells of the skeleton that carry out synthesis of new bone and that mediate regulation of bone activities.

Previtamin D An isomer of vitamin D formed during the irradiation process for producing vitamin D; it is in equilibrium with vitamin D.

Proximal convoluted tubule cells Cells lining the nephron leading from Bowman's capsule to the loop of Henle in the kidney.

RANKL A signal protein produced by osteoblasts and stromal cells in response to stimulants such as 1,25-(OH)₂D₃ and parathyroid hormone, and a ligand for the receptor activator for nuclear factor, kappa B, protein also known as the tumor necrosis factor-related activation-induced cytokine (TRANCE) or osteoprotegerin ligand.

Transcription factor A protein that controls whether genes are transcribed or not.

Vitamin D-dependent rickets Results from a mutation in either the 1 α -hydroxylase of vitamin D (type I) or the vitamin D receptor (VDR) (type II) that may respond to high levels of vitamin D depending on the site of mutation.

Vitamin D hormone The biologically active form of vitamin D₃ also referred to as 1 α ,25-dihydroxyvitamin D₃, 1,25-(OH)₂D₃, 1 α ,25-dihydroxycholecalciferol, and calcitriol.

Vitamin D-resistant rickets A disease in which rickets fails to respond to normal doses of vitamin D.

Chemical Identity, Natural Occurrence, and Production

The vitamin Ds are secosterols in which the B-ring of the steroid nucleus is replaced by a diene bridge and an exocyclic methylene group. The two most common forms are vitamin D₂ (ergocalciferol) and vitamin D₃ (cholecalciferol). The structures of these two nutritionally important compounds are illustrated in [Figure 1](#).

Although it is classified as a vitamin because of the nature of the discovery process, vitamin D in actual fact should not be considered a true vitamin for the following reasons. First and foremost, vitamin D utilized by higher organisms can be formed in the epidermis of skin by photolysis of 7-dehydrocholesterol, an intermediate in cholesterol biosynthesis. Second, vitamin D is nearly absent from the food supply. Vitamin D is found in fish liver oils, some fatty fish, and in egg yolk but is not found in virtually all plant materials, in skeletal meats, seeds, fruits, and vegetables. In fact, very little is found in an expected source, milk. We consider milk an important supply of vitamin D in many countries, primarily because it is fortified by the addition of vitamin D.

The chemical process whereby 7-dehydrocholesterol is converted to vitamin D₃ is well known. The 5,7-diene portion of either ergosterol or 7-dehydrocholesterol will absorb 280–310-nm ultraviolet light. This causes an isomerization to

form a compound, previtamin D₃, that in itself is biologically inactive and remains in skin. Previtamin D is in equilibrium with vitamin D₃ and, as the vitamin D₃ is formed, it is transported from the skin to the circulation. The plant sterol, ergosterol, is chemically converted to vitamin D₂ by an identical photolysis process. For many years, vitamin D₂ was the major synthetic form of vitamin D used in vitamin capsules, animal feeds, and in the fortification of foods. Because of improved synthetic chemical methods, vitamin D₃ has become the major form used for both fortification in the human food supply and nutrition of domestic animals. The photolysis of 7-dehydrocholesterol is quite efficient in skin, and summer sun exposure for 5–10 min will provide the daily requirement for vitamin D (20–30 $\mu\text{g d}^{-1}$) for optimal bone health. Winter sun is unable to induce production of vitamin D because of the angle of the sunlight and the filtration of the critical wavelengths that cause vitamin D production. It is generally accepted that skin production of vitamin D₃ is quantitatively the most important source of the vitamin for human health.

Conversion of Vitamin D to Its Hormonal Form

The vitamin D₃ that is produced in skin or that is absorbed from the intestine from vitamin pills or fortified foods is

biologically inactive as such. The body must process vitamin D to form a final vitamin D hormone that is believed to carry out all of the known functions of vitamin D. Vitamin D₃ is first hydroxylated, largely by the liver hepatocytes to form the circulating form of vitamin D₃, 25-hydroxyvitamin D₃ (25-OH-D₃). Interestingly, this compound is also biologically inactive at physiologic levels and must be further modified before function. The second step occurs in the proximal convoluted tubule cells of the kidney where a 1 α -hydroxyl group is added to the molecule to produce the final vitamin D hormone, 1 α ,25-dihydroxyvitamin D₃ (1,25-(OH)₂D₃). The reaction steps that result in this transformation are shown in Figure 2. At least two enzymes are known to hydroxylate vitamin D in the 25-position: a mitochondrial enzyme (CYP27A1) and a microsomal enzyme (CYP2R1), both of which have been cloned. The microsomal enzyme is likely the physiologically relevant 25-hydroxylase. Although a report of a human mutation in the CYP2R1 has appeared, this mutation does not prevent 25-hydroxylation, arguing that more than one enzyme can carry out this step. The 25-hydroxylation step appears largely unregulated. However, the second step occurring in the proximal convoluted tubule cells of the kidney is highly regulated. This 1 α -hydroxylase, also known as CYP27B1, has also been cloned and natural human mutants of this enzyme are now well known. These mutations result in a disease called vitamin D-dependent rickets type I, in which children present with vitamin D-deficiency disease, that is, rickets, hypocalcemia, and hypophosphatemia, even though

they are naturally irradiated with sunlight or are provided vitamin D as a supplement. These children are cured by the administration of physiologic amounts of the natural vitamin D hormone, 1,25-(OH)₂D₃, establishing clearly the two-step activation process of vitamin D for humans.

The Role of 1,25-(OH)₂D₃ in Calcium, Phosphorus, and Bone Metabolism

The basis for discovery of vitamin D in the first place is the disease rickets in children. This disease is also accompanied by hypocalcemia (low blood calcium) that causes convulsive tetany. In adults, the deficiency of vitamin D causes the disease, osteomalacia. The diseases, rickets and osteomalacia, result from a failure to mineralize the organic matrix of newly synthesized bone. Early investigations to understand how vitamin D functions were, of course, directed toward the formation of mineralized bone. However, it is now abundantly clear that 1,25-(OH)₂D₃ does not act directly on the mineralization process in the healing of rickets or osteomalacia but rather acts on intestine, kidney, and bone to provide calcium and phosphorus in the plasma required for the mineralization of skeleton and prevention of the convulsive disease, hypocalcemic tetany. The essence of vitamin D action, therefore, in curing rickets and osteomalacia is the elevation of plasma calcium and phosphorus to supersaturating levels that are required for normal mineralization. The vitamin D hormone acts to provide this calcium primarily by stimulating the enterocyte of the small intestine to absorb calcium as well as phosphate by an independent mechanism both of which require metabolic energy.

Because of the constant need for calcium to support normal neuromuscular function, calcium must be available in the plasma even when it is not available in the diet. The vitamin D hormone, that is, 1,25-(OH)₂D₃, acting together with parathyroid hormone will cause the mobilization of calcium from the skeleton into the plasma (bone resorption). Thus, the skeleton serves not only as a structural function but also as a reservoir of calcium and phosphorus. A final point is that 1,25-(OH)₂D₃ works in concert with the parathyroid hormone to induce the distal nephron of the kidney to reabsorb the last 1% of the filtered load of calcium into the plasma compartment. These systems then work to maintain plasma calcium and phosphate at levels that support both bone formation and

Figure 1 The nutritionally important forms of vitamin D. Vitamin D₃ is the form manufactured in skin and vitamin D₂ is the form produced by the irradiation of ergosterol. In mammals, both are equally active and appear to be metabolized by almost identical routes.

Figure 2 The required metabolism of vitamin D for function. Shown here is the metabolism of vitamin D₃ to the major blood form of vitamin D, 25-hydroxyvitamin D₃, and its subsequent metabolism in the kidney to form the final vitamin D hormone, 1 α ,25-dihydroxyvitamin D₃. It is this form of vitamin D₃ that carries out all of the known functions of the vitamin and its production is very tightly regulated. Vitamin D₂, not shown here, is metabolized in an almost identical fashion to its active form, 1 α ,25-dihydroxyvitamin D₂.

Figure 3 A diagrammatic representation of how the vitamin D hormone ($1,25\text{-(OH)}_2\text{D}_3$) functions to maintain plasma calcium at supersaturating levels which are required for the prevention of hypocalcemic tetany (neuromuscular) and for the prevention of rickets and osteomalacia (mineralization of bone).

prevent hypocalcemic tetany. A diagram representing these functions is shown in [Figure 3](#).

The Vitamin D Endocrine System

One of the most elegantly regulated substances in the body is plasma calcium. The parathyroid glands continuously monitor plasma calcium levels, and a G-protein-coupled calcium-sensing receptor therein responds when calcium falls even slightly below normal. This leads to the secretion of parathyroid hormone, a peptide hormone, that is the body's signal requesting calcium. It binds to the entire nephron of the kidney and to the osteoblasts of bone and, among its functions in the kidney, it stimulates the 1α -hydroxylase (CYP27B1) to produce the vitamin D hormone. The vitamin D hormone then acts on the bone, kidney, and intestine as described above to mobilize calcium to raise blood calcium into the normal range, clearing the set point of the parathyroids shutting down parathyroid secretion. Overshoot of calcium results in the C-cells of the thyroid secreting calcitonin, a 32-amino-acid peptide hormone that blocks calcium mobilization from the skeleton. Calcitonin also has a stimulatory effect on the 1α -hydroxylase to produce the vitamin D hormone in small amounts to support its non-calcemic activities described in the following.

The Vitamin D Receptor

$1,25\text{-(OH)}_2\text{D}_3$ is a true steroid hormone that acts through a nuclear receptor called the vitamin D receptor (VDR). The human receptor is a 427-amino-acid protein that serves as a ligand-dependent transcription factor. It is a member of the nuclear receptor superfamily of receptors. Other members of this superfamily include the retinoic acid, thyroid, estrogen, androgen, glucocorticoid, and other steroid hormone receptors. VDR is the smallest of the steroid hormone receptors and largely acts in a fashion quite similar to other class II nuclear

receptors. Unlike other nuclear receptors, there is only a single VDR in the target tissues. No subtypes are known and it is this receptor through which all known vitamin D actions occur. Natural mutants of the human VDR are known and produce a disease called vitamin D-dependent rickets type II. In this disease, high blood levels of $1,25\text{-(OH)}_2\text{D}_3$ occur in the face of severe rickets and severe hypocalcemia and hypophosphatemia. VDR-null mutant mice have been produced and are available as experimental tools, and these mice largely phenocopy the most severely affected patients. The vitamin D-dependent rickets type II patients vary in disease severity depending upon where in the VDR the mutation has occurred. If there is a complete absence of a functional receptor, then very brittle vitamin D-resistant rickets occurs and can only be treated by the infusion of calcium and phosphorus into the blood stream to mineralize the skeleton, but many of the other functions of vitamin D go unmet. The fact that VDR-null mutant mice are approximately normal at birth shows that vitamin D does not play a major role in embryonic development but functions primarily after parturition.

There are reports of nongenomic functions of vitamin D. These have been largely cellular-based observations which have yet to be shown to occur *in vivo*. The administration of large amounts of $1,25\text{-(OH)}_2\text{D}_3$ to VDR-null mutant mice produces no significant phenotype, suggesting that the only mechanism of action of the vitamin D hormone is through its receptor under physiologic circumstances.

Molecular Mechanism

Vitamin D-response elements (VDREs) are found in the promoter region of target genes and more recently have been located at sites quite distant from the promoter. These VDREs are hexameric repeats (although the sequences are usually not exact repeats) separated by three nonspecified bases. Although response elements with two repeats are most common, more complex response elements have been described. The VDR must heterodimerize with another transcription factor, the retinoid X receptor (RXR), in order to bind to the responsive elements. The RXR binds to the 5' repeat and the VDR to the 3' repeat. [Figure 4](#) provides a cartoon to illustrate what is currently known about the mechanism of action of the vitamin D hormone working through its receptor to regulate expression of target genes. As with other class II nuclear receptors, it is anticipated that the unliganded receptor may be retained in an inactive state by being bound to a corepressor complex. This has not been specifically shown for the VDR but is known for other class II nuclear receptors. Binding of the ligand would cause a release of the corepressor. The receptor would then be free to interact with a coactivator protein that is believed to be involved in chromatin remodeling and to link the complex bound at the hormone response element to the basal transcription machinery. Among the known coactivators believed to interact directly with the VDR are steroid receptor coactivator (SRC) 1, 2, 3 and vitamin D-interacting protein 205 (DRIP 205). Likely, other participating coactivators will be discovered. A phosphorylation does occur on serine 205 of the VDR but whether this is of functional importance remains to be

Figure 4 A cartoon representing the molecular mechanism of action of the vitamin D hormone (1,25-(OH)₂D₃) in regulating transcription of target genes in the target tissues. Binding of the ligand, that is, 1,25-(OH)₂D₃ to the VDR/RXR, causes a conformation change of the VDR enabling binding of a coactivator complex leading to chromatin remodeling and enhanced gene transcription. Several proteins are required to form the transcription complex, all of which have not yet been identified. There is a bending of the DNA and a phosphorylation on serine-205 but their exact role in either suppression or activation of transcription remains unknown. VDRE, vitamin D hormone response element; TATA, a consensus sequence of thymine/adenine found in the promoter region of most genes that seems important in determining accurately the position at which transcription is initiated; TFIIB, transcription factor IIB; TFIID, transcription factor IID; RNAPII, ribonucleic acid polymerase II.

determined. More recently, additional VDRE sites have been located on target genes that act as enhancers of gene transcription. These enhancers are believed to act in a three-dimensional sense to recruit and increase effectiveness of transcription machinery. The mechanism whereby the VDR–RXR heterodimer regulates gene suppression is less well understood.

Metabolism and Degradation

The vitamin D hormone is degraded specifically by an enzyme it induces. This enzyme is the CYP24A1 (24-hydroxylase) which carries out a series of reactions on the side chain of the vitamin D hormone and its precursor, 25-OH-D₃. It first causes hydroxylation of the 24R-position, followed by oxidation of that same hydroxyl to a ketone. The next step again carried out by the same enzyme is a 23-hydroxylation, followed by cleavage and oxidation, giving rise to the biliary excretion product called calcitroic acid in the case of 1,25-(OH)₂D₃. Calcitroic acid is biologically inactive. 25-OH-D₃ is believed to be converted in analogous steps to the corresponding C-23 acid or 1-deoxycalcitroic acid. Thus, the vitamin D hormone, an extremely potent biological substance, ensures its limited activity by inducing its own destruction. Other metabolism of 1,25-(OH)₂D₃ and 25-OH-D₃ is known, including the formation of the 26,23-lactone derivative, 26-hydroxylation; however, quantitatively the most important reaction regulating the level of vitamin D hormone is carried out by the CYP24A1. The CYP24A1 is regulated in a negative fashion by parathyroid hormone causing an instability of the messenger RNA (mRNA) encoding for that enzyme. Thus, the parathyroid hormone not only stimulates the 1 α -hydroxylase but also stimulates the destruction of the enzyme that destroys the

hormone, thereby ensuring large amounts of the vitamin D hormone are available to carry out its calcium functions.

New and Nonclassical Roles of the Vitamin D Hormone

With the discovery of the VDR came the observation that it is found in tissues not previously appreciated as target tissues of vitamin D action. The discovery of the VDR in the intestine, kidney tubules, and osteoblasts was not unexpected. However, its presence in the parathyroid gland, the islet cells of the pancreas, the immune cells such as T-cells and macrophages, keratinocytes, and other cells made it possible that the vitamin D hormone had important functions besides raising blood calcium and phosphate and mineralizing the skeleton. It is now clear that an important function of the vitamin D hormone is to suppress the growth of parathyroid glands and to suppress production of the parathyroid hormone. Physicians have taken advantage of this basic function when using 1,25-(OH)₂D₃ and its analogs to treat secondary hyperparathyroidism in patients with kidney failure.

Other important VDR sites include the promyelocytes which are the precursors of the monocyte. The vitamin D hormone stimulates differentiation of the promyelocyte to the monocyte. It also stimulates RANKL production by osteoblasts and stromal cells. RANKL catalyzes the formation of giant osteoclasts that are responsible for bone resorption. It also activates resting or inactive osteoclasts. This results in bone resorption, the first step in bone remodeling. 1,25-(OH)₂D₃ also induces new bone formation by the osteoblast, thus playing an important role in both arms of the bone remodeling system.

The role of the vitamin D hormone in the keratinocyte also has therapeutic importance. The vitamin D hormone

added to the keratinocytes in cultures has been shown to inhibit cell proliferation and promote differentiation. Thus, $1,25\text{-(OH)}_2\text{D}_3$ and analogs have been successfully used in the topical treatment of psoriasis, a disease of hyperproliferation of the keratinocytes.

Finally, attention must be focused on the immune system where the vitamin D hormone is now known to cause important immunomodulatory effects. The vitamin D hormone can be used to block certain animal models of autoimmune disease. For example, it can be used to prevent experimental autoimmune encephalomyelitis (EAE), a model of multiple sclerosis in mice. However, the level of $1,25\text{-(OH)}_2\text{D}_3$ required also induces an abnormal rise in serum calcium. $1,25\text{-(OH)}_2\text{D}_3$ can also prevent diabetes in the nonobese diabetic mouse model of type I diabetes. It can be used to prevent disease in animal models of rheumatoid arthritis, systemic lupus, and inflammatory bowel disease. Although there is a great deal of effort being expended, the exact role of the vitamin D hormone in the immune system remains unclear.

Therapeutic Uses of $1\alpha,25\text{-(OH)}_2\text{D}_3$ and Its Analogs

As pointed out above, besides the treatment of vitamin D-dependent rickets type 1 and vitamin D-resistant rickets of many types, the vitamin D hormone and its analogs are certainly central actors in the treatment of bone disease secondary to kidney failure. This is primarily by suppression of parathyroid proliferation and by suppression of parathyroid hormone production. $1,25\text{-(OH)}_2\text{D}_3$ and its analog, $1\alpha\text{-OH-D}_3$, have been successfully used in certain parts of the world to treat postmenopausal and age-related osteoporosis, giving a modest rise in bone mass along with a clear reduction in fracture rate. The danger of hypercalcemia has limited their use in the treatment of this disease. However, newer vitamin D analogs with greater bone anabolic activity than $1,25\text{-(OH)}_2\text{D}_3$ are currently under development and may make it possible to safely treat osteoporosis in the future.

An analog of $1,25\text{-(OH)}_2\text{D}_3$ called Dovonex[®] is currently marketed for the topical treatment of the hyperproliferative skin disorder, psoriasis. Improved analogs will likely appear for the treatment of psoriasis. There are potential new uses for vitamin D analogs in the autoimmune diseases as described

above or in the treatment of malignant cancer growth. The vitamin D hormone has been found to suppress growth of malignant cells *in vitro* and to cause their differentiation into functional cells. Thus, the use of vitamin D compounds as a potential treatment of neoplastic disease has been exciting but it has not yet yielded a therapeutic agent. The major problem with the use of $1,25\text{-(OH)}_2\text{D}_3$ and many of its analogs for the treatment of disease is that its primary purpose is to raise blood calcium and phosphorus, which means that hypercalcemia is a major side effect that must be eliminated before an analog can be used to treat noncalcemic diseases. One approach to this is the synthesis of analogs that retain the ability to suppress cancerous growth but do not raise blood calcium. New analogs with these desirable characteristics are currently under basic study, but are not yet available for pharmaceutical use.

Glossary

Comodulatory proteins Proteins that interact directly with the nuclear receptor and alter the transcriptional regulatory activity of the receptor. Coactivators enhance the activity of the receptor, and corepressors attenuate the transcriptional regulatory activity of the receptor.

Histone acetyltransferase (HAT) Enzymes that add acetyl groups to the positively charged lysine residues on core histones, effectively negating the positive charge. Histone hyperacetylation is correlated with areas of active transcription, while hypoacetylation is correlated with nontranscribed promoters.

1,25-Dihydroxyvitamin D₃ (1,25(OH)₂D₃) The active form of vitamin D in mammals.

Preinitiation complex (PIC) The complex of basic transcription factors that are necessary and sufficient for the

initiation of transcription to occur. In addition to RNA polymerase II, the PIC consists of transcription factor IIA (TFIIA), TFIIB, TFIIE, TFIIIF, and TATA-binding protein or TBP.

Retinoid X receptor (RXR) A member of the nuclear receptor superfamily of transcription factors that serves as a common heterodimeric partner for many of the class II nuclear receptors, including retinoic acid receptor, vitamin D receptor (VDR), thyroid hormone receptor, and peroxisome proliferator-activating receptor.

Vitamin D responsive elements (VDRE) Specific sequences of DNA that the VDR–RXR heterodimer selectively recognize and bind. This binding event is one of the initial steps in the mechanism through which 1,25-dihydroxyvitamin D₃ and the VDR regulate gene transcription.

Introduction

Vitamin D₃, or cholecalciferol, was discovered nearly a century ago as a micronutrient that is essential for normal skeletal development and for maintaining bone integrity. 1,25(OH)₂D₃ is the bioactive, hormonal form of vitamin D. However, vitamin D₃ is more appropriately classified as a hormone because it is produced in the body in response to serum calcium levels and it functions through a mechanism that is analogous to other steroid hormones. 1,25(OH)₂D₃ is generated by two sequential hydroxylations of vitamin D₃ in response to hypocalcemia and elevated parathyroid hormone. The predominant role of 1,25(OH)₂D₃ is to enhance the intestinal absorption of dietary calcium and phosphorus. 1,25(OH)₂D₃ also acts on mineral-regulating target tissues such as intestine, bone, kidney, and parathyroid glands to maintain normal calcium and mineral homeostasis. 1,25(OH)₂D₃also directly affects skeletal bone remodeling by causing osteoblasts to terminally differentiate into osteocytes and deposit calcified matrix. 1,25(OH)₂D₃also promotes the differentiation of precursor cells into mature osteoclasts which function to resorb bone and maintain appropriate bone remodeling. Thus, it is through an integrated series of diverse effects that vitamin D is thought to preserve and maintain the integrity of the bony tissues. To highlight this role, vitamin D₃ deficiency leads to rickets in children and osteomalacia in adults. The vitamin D endocrine system is also involved in a number of other important physiological processes including blood pressure regulation, immune function, mammary gland development, hair follicle cycling, and protection against chemical and ultraviolet light-induced skin tumorigenesis.

The biological effects of 1,25(OH)₂D₃ are mediated through a soluble receptor protein termed the vitamin D receptor (VDR), a member of the steroid receptor or nuclear receptor (NR)

superfamily. The VDR binds 1,25(OH)₂D₃ with high affinity and high selectivity. In the target cell, the interaction of the 1,25(OH)₂D₃ hormone with VDR initiates a complex cascade of molecular events culminating in alterations in the rate of transcription of specific genes or gene networks (Figure 1). Central to this mechanism is the requisite interaction of VDR with retinoid X receptor (RXR) to form a heterodimeric complex. The dimer binds to specific DNA sequence elements (vitamin D-responsive elements (VDREs)) in vitamin D-responsive target genes and ultimately influences the rate of RNA polymerase II-mediated transcription. An important concept in this mechanism is that protein–protein interactions between the VDR–RXR heterodimer, transcriptional comodulatory proteins and the transcription machinery are essential for the mechanism of vitamin D-mediated gene expression. This article discusses the molecular biology of the VDR with a focus on the macromolecular interactions that are required for the transcriptional regulatory activity of the VDR.

Functional Domains of the VDR

The N-Terminal DNA-Binding Domain

Receptors in the NR superfamily generally have two transcriptional activation domains, termed activation function (AF) 1 and 2, which are required for the receptor to function as a ligand-activated transcription factor. The AF-2 domain exists at the extreme COOH terminus, while the AF-1 domain is located in the N-terminal region (or A/B domain) of the receptors (Figure 2). The AF-1 domain is a constitutive (i.e., hormone-independent) activation domain. In the VDR, the N-terminal A/B domain is truncated compared to other NRs and, thus, an analogous constitutive AF-1 domain is lacking in the VDR.

For VDR to regulate transcription of target genes, it must recognize and bind to DNA in the promoter regions of vitamin D-responsive genes. It does so through a specialized DNA-binding domain (DBD) located near the amino terminus of the receptor (Figure 3). This DBD is required for the VDR to bind selectively and with high affinity to specific DNA sequences termed VDREs. The minimal DBD of the VDR that mediates VDR–DNA interactions resides between amino acid residues 22 and 113 in the human sequence. There are nine cysteine residues within the DBD that are conserved throughout the family members. The first eight of these cysteines (counting from the N terminus) tetrahedrally coordinate two zinc atoms to form two zinc-finger DNA-binding motifs. Mutation of the first eight of the nine cysteine residues to serines eliminates VDR binding to both nonspecific and specific DNA sequences and eliminates VDR-mediated transactivation. Indeed, inactivating mutations within the DBD of the human VDR are responsible for the rare-inherited disorder termed vitamin D-resistant rickets type II. These patients express a nonfunctional VDR that cannot bind to DNA, and they exhibit classical symptoms of vitamin D deficiency that are not corrected by providing an external source of vitamin D.

Ligand-Binding Domain

The large carboxyl-terminal ligand-binding domain (LBD) of VDR is organized into 12 α -helices. As the name suggests, the LBD is responsible for high-affinity binding of the 1,25(OH)₂D₃ ligand, exhibiting equilibrium binding constants of the order of 10^{-10} – 10^{-11} M. Both the 1-hydroxyl and 25-hydroxyl moieties are crucial for efficient recognition by VDR, and the nonhydroxylated, inactive parent vitamin D₃ compound does not bind appreciably to the VDR.

In addition to hormone binding, the LBD is required for several other aspects of receptor function, particularly in mediating protein–protein interactions. One important protein–protein contact is the heterodimerization of VDR with the RXR. As mentioned above, VDR–RXR heterodimer formation is generally required for high-affinity interaction of the receptor with VDREs and an extensive heterodimerization interface that coalesces around helices 10 and 11 in the LBD of VDR mediate protein–protein contacts with RXRs.

The LBD also mediates association of VDR with comodulatory proteins. Many of these interactions occur at the extreme C-terminus of the receptor, where the AF-2 domain is located (Figure 2). The AF-2 domain is highly conserved throughout the hormone receptor superfamily and its main structural

Figure 1 Mechanism of action of the vitamin D receptor. VDR binds to its ligand, 1,25(OH)₂D₃, heterodimerizes with RXR, and binds to a DR-3 type VDRE in the promoter of 1,25(OH)₂D₃-responsive genes. VDR occupies the proximal or 3' half-site, while RXR occupies the distal or 5' half-site. VDR/RXR then recruits coactivators such as SRCs and p300/CBP. The HAT activity of these coactivators loosens the chromatin structure, allowing for a more transcriptionally permissive environment. SRCs and p300/CBP dissociate, allowing for binding of other coregulatory proteins including and the Mediator-D multimeric complex. This latter complex is thought to recruit RNA Pol II and the core transcriptional machinery to initiate active transcription of the target gene.

feature is that of an amphipathic α -helix. Removing 25 amino acids from the C-terminus of hVDR ($\Delta 403$ –427), which contains the AF-2 domain, results in a complete loss of $1,25(\text{OH})_2\text{D}_3$ /VDR-activated transcription. This loss of function is not due to altered binding of RXR, VDRE, or hormone and the mutant receptor was appropriately targeted to the cell nucleus. Thus, the AF-2 domain of VDR, corresponding to helix 12, plays a central role in $1,25(\text{OH})_2\text{D}_3$ -activated transcription mediated by VDR.

Molecular Mechanism of Transcriptional Control by VDR

VDR Interaction with VDREs

VDR modulates transcription by binding to specific VDREs, in the promoter regions of responsive genes. VDREs from a variety of target genes have been identified and on this basis, a consensus VDRE may be generally described as an imperfect direct repeat of a core hexanucleotide sequence, G/A G G T G/C A , with a spacer region of three nucleotides separating each half element (also termed DR-3 for direct repeat with a three nucleotide spacer). The mechanism of VDR binding to VDREs is reflected in the direct repeat nature of the element. For example, purified VDR alone does not bind to a VDRE with high affinity. Rather, RXR is required for high-affinity binding of

VDR to VDREs. The asymmetry of the directly repeating motif causes the VDR–RXR heterodimer to bind to the VDRE with a defined polarity, with RXR occupying the 5' half-site and VDR occupying the 3' half-site.

One important role for the $1,25(\text{OH})_2\text{D}_3$ ligand in the transactivation process is to dramatically enhance both the formation of the VDR–RXR heterodimer and the subsequent interaction of the heterodimer with the VDRE (Figure 1). Upon ligand binding, there is a clear $1,25(\text{OH})_2\text{D}_3$ -dependent decrease in the formation of VDR homodimers and a concomitant increase in VDR heterodimerization with RXR. These ligand-induced changes in VDR–RXR interactions are likely due to altered conformations of the VDR that disrupts weak homodimers of unliganded VDR and promotes liganded VDR heterodimerization with RXR. The interaction of VDR and RXR generates a heterodimeric complex that is highly competent to bind DR-3-like VDREs and subsequently affect the transcriptional process. Thus, the VDR–RXR heterodimer is the primary active complex involved in controlling DR-3 VDRE-driven promoters. Interestingly, VDREs may function over very long distances. A concept is emerging in which VDREs exist at sites that are extremely distal (>50 kb) to the transcriptional start site and at sites both upstream and downstream of the start site.

The natural VDREs identified thus far provide only a snapshot of the DNA sequences that mediate the transcriptional effects of the VDR. Variations on the DR-3 motif for VDREs have been identified in the elements that mediate vitamin D responsiveness in the calbindin D_{9k} and calbindin D_{28k} genes. Moreover, several synthetic elements with large spacer regions and inverted arrangements can mediate vitamin D responsiveness under certain conditions. It is likely that the affinity of VDR for these atypical elements may vary from that of the classic DR-3 motif adding yet another level of regulatory complexity to the process of VDR-mediated gene expression.

Other variations of the VDRE can lead to the specific downregulation of gene expression. Both the rat PTH promoter

Figure 3 Schematic of the DNA-binding domain of the VDR. The cysteines responsible for coordinating the zinc atoms are shown in red.

and the human PTHrP promoter contain negative VDREs (nVDREs) which closely resemble the consensus VDRE sequence. These nVDREs are bound by either VDR homodimers or by VDR/RXR heterodimers and subsequently down-regulated. A second type of nVDRE, composed of E-box type motifs (5'-CATCTG-3'), was identified in the promoters of the human CYP27B1 gene, the human PTH gene, and the human PTHrP gene. These nVDREs are bound by a helix-loop-helix transcription factor known as VDR-interacting repressor and are transcriptionally active in the absence of $1,25(\text{OH})_2\text{D}_3$. When $1,25(\text{OH})_2\text{D}_3$ is absent, VDR recruits CBP/p300 HAT activity to promote transcription. However, in the presence of $1,25(\text{OH})_2\text{D}_3$, liganded VDR/RXR heterodimers associate with the nVDRE-bound VDR-interacting repressor, resulting in the dissociation of the CBP/p300 HAT coactivator and the recruitment of histone deacetylases and NCoR/SMRT corepressors. Thus, the chromatin is subsequently remodeled and transcription inhibited.

Communication between VDR and the Transcriptional Machinery

The regulation of VDR-mediated transcription involves a complex series of macromolecular interactions occurring in a temporally coordinated fashion (Figure 1). Other transcriptional components that associate with the liganded VDR/RXR heterodimer may be classified into two general categories: general transcription factors and the comodulatory proteins. The interaction of VDR with the first group results in direct contacts with the preinitiation complex (PIC), which may facilitate assembly or recruitment of the PIC and thereby stimulate transcription by RNA Pol II. Transactivator interaction with the PIC may occur via adapter proteins such as the TATA-binding protein-associated factors or via direct interaction with other core transcription factors. In this regard, TFIIB may be a key target because it is known to interact directly with VDR and augment vitamin D-activated transcription in transient gene-expression studies. Indeed, differences in the activities of NH₂-terminal VDR isoforms are attributed to differential interactions with TFIIB, thus, supporting an important role for the VDR-TFIIB interaction in determining the overall transactivation potential of the liganded VDR.

In addition to direct contacts with the general transcription machinery, the liganded VDR is also linked to the transcriptional PIC by the NR comodulatory factors. The general functional properties of the NR comodulators are their ability to interact with NRs and control their transcriptional responsiveness to ligand. NR comodulators are classified either as coactivators or corepressors, and they aid in the induction or repression, respectively, of ligand/receptor-mediated transcription. NR coactivators may function as macromolecular bridges between the receptor and the transcriptional machinery that aid in the assembly or promote the stability of the PIC. Moreover, several coactivator proteins either possess intrinsic histone acetyltransferase (HAT) activities or recruit other proteins that possess HAT activity (e.g., CBP/p300). Acetylation of histones near the promoter presumably results in a loosening of chromatin structure and greater accessibility of the promoter for the transcriptional machinery (Figure 1). The best-characterized coactivators are the steroid receptor

coactivator (SRC) family of NR coactivators that includes three members at present: SRC-1 (NCoA-1), SRC-2 (GRIP-1, TIF2, NCoA-2), and SRC-3 (pCIP, RAC3, ACTR, AIB-1, TRAM-1).

Structural studies of related receptors provide insight into the mechanism of ligand-induced interaction of VDR with SRC coactivators. It is hypothesized that the $1,25(\text{OH})_2\text{D}_3$ ligand promotes coactivator interaction by inducing a repositioning of the AF-2 activation helix, or helix H12 (Figure 4). In the unliganded state, the AF-2 domain (helix H12) projects out away from the globular core of the LBD, while in the liganded state the AF-2 domain is folded over onto the LBD globular core domain. One outcome of helix H12 folding is the creation of a platform or protein interaction surface through which coactivator proteins such as SRCs effectively dock with the VDR. The domain in the coactivator proteins, which is responsible for this interaction is termed the NR or NR box and is an amphipathic α -helix composed of the consensus core sequence LXXLL. This interaction is essential for transactivation mediated by the VDR.

A large multiprotein complex called Mediator D is another coactivator required for VDR-mediated transcription (Figure 1). Mediator D is also known as VDR-interacting protein (DRIP), thyroid receptor-activating protein complex, and the mammalian mediator complex. The Mediator D complex is composed of at least 10 different proteins anchored by Med220, which interacts directly with ligand-activated VDR/RXR heterodimers through one of two LXXLL motifs. DRIP is essential for *in vitro* VDR-mediated transcription from chromatinized templates. However, as the DRIP complex does not contain any SRCs and does not possess HAT activity, it appears to potentiate NR-mediated transcription through distinct mechanisms. In particular, DRIP directly recruits the RNA polymerase II holoenzyme to $1,25(\text{OH})_2\text{D}_3$ -activated VDR, indicating that DRIP may serve as a bridge between VDR and the core transcriptional machinery. Indeed, chromatin immuno-precipitation studies show that DRIPs enter transcriptional complexes at a later time than SRC coactivators, supporting the nonredundant roles of these coactivator classes in NR-mediated transactivation.

Numerous other classes of comodulators have been described that interact through distinct mechanisms and impinge on VDR-mediated transcriptional regulation at proximal and distal steps in the process. One example is NCoA62/SKIP, a unique VDR coactivator protein that lacks LXXLL motifs and that selectively interacts with the VDR-RXR heterodimer in an AF2-independent manner. NCoA62/SKIP enters the transcriptional regulatory complex following SRCs and the mediator complex. Indeed, its close association with the RNA spliceosome complex and functional studies indicate a role for

Figure 4 The vitamin D receptor undergoes a conformational change upon binding hormone. The VDR binds ligand and this induces a conformational change in the AF-2 domain to trap the ligand in the binding pocket. This change also creates a hydrophobic cleft or surface on VDR that LXXLL motifs in coactivator proteins use for docking to the VDR.

NCoA62/SKIP in the splicing of nascent RNA transcripts that result from the process of VDR-activated transcription. Thus, NCoA62/SKIP represents a class of coactivators that may function at distal steps in the mechanism of NR-mediated transcription by coupling two global processes in the nucleus, transcription and RNA processing. The combined actions of the variety of distinct classes of comodulatory proteins ensure efficient and rapid responses of the cell to vitamin D and VDR-mediated transcription regulation.

Summary

Research spanning the past 25 years reveals that $1,25(\text{OH})_2\text{D}_3$ -mediated transcription is more complex than the simple binding of the receptor to DNA and the recruitment of RNA Pol II to initiate transcription. VDR/RXR-activated transcription involves complex interactions that may occur in a spatially distinct and temporally coordinated fashion to increase the rate at which $1,25(\text{OH})_2\text{D}_3$ -responsive genes are transcribed and at which the resulting RNA transcript is processed. A model for VDR-mediated transcription is proposed which incorporates numerous properties of VDR that were discussed in this section (Figure 1). The initial event in this model is high-affinity binding of the $1,25(\text{OH})_2\text{D}_3$ ligand to the VDR. Ligand binding induces VDR/RXR heterodimerization and the heterodimer specifically binds VDREs in the promoter regions of vitamin D-responsive genes. The heterodimer then recruits coactivator molecules that acetylate core histones to make the DNA more accessible to the transcriptional machinery. Meanwhile, other coactivators and the PIC are recruited to the site and activated transcription proceeds. Understanding the complex interplay that occurs between these various factors is crucial to unraveling the complexities of activated or repressed transcription mediated by vitamin D and the VDR.

Glossary

RRR- α -tocopherol The only stereoisomer of α -tocopherol occurring in nature. When α -tocopherol is made by chemical synthesis, it contains not only the RRR-stereoisomer, but also a racemic mixture (called all-*rac*- α -tocopherol) of eight stereoisomers. Synthetic α -tocopherol is mainly used in dietary supplements and in fortified foods.

Tocopherol transfer protein (TTP) A protein expressed primarily in liver and to a lesser degree in the brain and placenta. TTP binds RRR- α -tocopherol with high affinity and

selectivity, and is responsible for the enrichment of plasma with this form of the vitamin.

Vitamin E The term denoting a group of eight neutral lipids of plant origin, including four tocopherols and tocotrienols. α -Tocopherol is the most prominent form of vitamin E, which is considered not only essential in humans and animals, but also the major functional lipid-soluble antioxidant in humans, protecting against oxidative damage to lipids in circulation and in cell membranes.

Vitamin E: Definition and Structures

Vitamin E refers to a group of structurally related plant-derived natural products comprised of tocopherols and tocotrienols. The four tocopherols and four tocotrienols (together called tocols) differ from each other by the number and placement of methyl groups on a parent 6-hydroxychroman (**Figure 1**). The naturally occurring tocopherols have 2*R*,4'*R*,8'*R* (RRR) stereochemistry, while the tocotrienols have only the one center of *R*-stereochemistry at C2. By contrast, synthetic α -tocopherol consists of a racemic mixture of eight stereoisomers (four enantiomeric pairs: RRR-SSS, RSR-SRS, RRS-SSR, and RSS-SRR) arising from the three chiral centers at positions C2, C4', and C8'' and is designated as all-*rac*- α -tocopherol (or *dl*- α -tocopherol). The tocotrienols have three sites of unsaturation on the side chain at carbons 3', 7', and 11'.

Biological Activity

In the 1950s, it was recognized by A.L. Tappel's group that vitamin E is the body's major lipid-soluble antioxidant. The physicochemical basis of this activity was later described in detail by K.U. Ingold and G. Burton, E. Niki, and K. Fukuzawa. It is now accepted that vitamin E inhibits the free radical-chain peroxidation of polyunsaturated lipids in membranes and lipoproteins. The lipids that are most susceptible to peroxidation are those containing *bis*-allylic methylenes, CH₂-groups between two *cis*-double bonds in fatty acid structures (**Figure 2**). The greater the number of these sites, the more prone the lipid is to peroxidation. Thus, the polyunsaturated linolenic, arachidonic, and docosahexaenoic acids are examples of lipids sensitive to peroxidation. All natural forms and synthetic stereoisomers of vitamin E exhibit to varying degrees the ability to inhibit lipid peroxidation as chain-breaking antioxidants. Antioxidant activities of tocols are greater in solution than in lipid membranes, but the rank order of antioxidant activities remains $\alpha > \beta \approx \gamma > \delta$ for both substrate presentations.

It is worth noting that all forms of tocopherol are excellent antioxidants *in vitro*, but that α -tocopherol is superior. α -Tocopherol is approximately twice as efficient a radical quencher as γ - and β -tocopherol, and about 5 times better than δ -tocopherol in chemical measures of antioxidant activity. These findings likely have little relevance to *in vivo* biological activity, as selective distribution and metabolism of dietary tocols heavily favor the retention of α -tocopherol in tissues.

The nature of the initiating radical R• in **Figure 2** is often considered to be reactive oxygen and nitrogen species, but the rates of H-atom abstraction from susceptible lipids by many of these species are very slow. *In vivo*, the most relevant species is most likely the protonated form of superoxide (the perhydroxyl radical HOO•) whose acid dissociation constant (pK_a) is ~ 4.9 and thus is still present ($\sim 0.5\%$) at physiological pH. The fact that HOO• is charge neutral also facilitates its access to the hydrophobic portion of membranes. The role of spontaneously formed lipid hydroperoxides is known to be critical in chemical systems and may also play a role *in vivo*.

The peroxidation of membrane lipids is nonreversible. Lipid hydroperoxides and their breakdown products such as 4-hydroxynonenal and malondialdehyde are known to react with and modify the activity of cell proteins. The selective loss of polyunsaturated fatty acids in phospholipids can also change membrane structure and lower membrane fluidity – critical elements of membrane function. Each molecule that suffers oxidation will eventually be removed from membranes by the action of peroxide reductases, lipases, and esterases.

Most of the research explaining the antioxidant activity of tocols has been performed *in vitro*, often in organic solvents, or in lipid dispersions that may not be perfect models for the biological membranes where vitamin E is found *in vivo*. Biological membranes are now known to be heterogeneous, with portions enriched in certain lipid types, including the so-called lipid rafts rich in saturated lipids, sphingomyelin, and cholesterol, and other portions rich in polyunsaturated lipids where tocopherol has been observed to concentrate. This heterogeneity is difficult to reproduce *in vitro* and

The four naturally occurring forms of tocopherols and tocotrienols

Figure 1 The molecular structures of vitamin E. Tocopherols and tocotrienols exist in four different forms (α -, β -, γ -, and δ -forms) that differ by the extent and position of methyl groups on the chromanol ring. Tocopherol is shown in its naturally occurring *RRR*-configuration.

Figure 2 Simplified scheme illustrating the initiation of lipid peroxidation at *bis*-allylic centers on polyunsaturated lipids by a free radical $R^\bullet$, the formation of lipid peroxy radicals (that can abstract an H-atom and continue the chain reaction), and the radical chain termination of a lipid peroxy radical by tocopherol. The α -tocopheroxyl radical can be recycled to α -tocopherol by a one-electron reduction and the reducing agent *in vivo* is thought to be ascorbate. Further one-electron oxidation of the tocopheroxyl radical produces tocopheryl quinone.

complicates kinetic models. Because of technical issues in following short-lived radical species, chemical evidence for the action of vitamin E as a radical chain terminating antioxidant *in vivo* is indirect, relying on the analysis of lipid oxidation products such as 4-hydroxynonenal or malondialdehyde. Earlier products of polyunsaturated lipid peroxidation such as the F_2 -isoprostanes (rather than breakdown products such as

malondialdehyde) are now considered more reliable measures of oxidative stress.

Other biological activities have been reported for tocopherols (mainly α - and γ -tocopherols) and tocotrienols (α - and δ -forms) that may or may not be dependent on their action as antioxidants, including the regulation of cell cycle, apoptosis, and gene expression.

Vitamin E in Health and Disease

The first biological activity ascribed to vitamin E is that of a fertility factor that restored reproductive function to diet-restricted female rodents (hence the name tocopherol; from the Greek 'tocos' (offspring) and 'pherein' (to bring forth)). This protective action was also used to establish that RRR- α -tocopherol is the most biologically active member of the vitamin E family. In the decades since, the critical roles that vitamin E plays in many other biological processes have been established. In accordance with the function of vitamin E as an important antioxidant, the requirement for tocopherol is primarily evident from pathologies that involve a significant redox imbalance. It is important to note that since dietary deficiency of vitamin E is extremely rare in humans, our appreciation of its role in health relies primarily on studies in animal models.

Central Nervous System

The clearest manifestation of vitamin E deficiency is in disturbances of the nervous system. Human carriers of mutations in the tocopherol transfer protein (TTP, see below) present ataxia with vitamin E deficiency (AVED) – a debilitating disorder characterized by progressive ataxia (loss of movement coordination) and low serum vitamin E levels. The neurological damage appears to originate from loss of Purkinjee cells in the cerebellum. If treated at an early stage, AVED symptoms can be normalized by supplementation with high doses of vitamin E. Genetic animal models of vitamin E deficiency (i.e., TTP^{-/-} mice) display neurological symptoms similar to those of human AVED patients that can be prevented by timely supplementation with α -tocopherol. Adequate vitamin E status is also thought to be important for the prevention and treatment of other neurological disorders accompanied by an oxidative stress component, such as Parkinson's disease and Alzheimer's disease, and supplementation with α -tocopherol is often recommended to patients affected with these disorders.

Coronary Heart Disease

Atherosclerosis is a critical component in the etiology of coronary heart disease (CHD), the leading cause of death in the US. The lipid oxidation theory holds that the formation of atherosclerotic plaques is triggered and precipitated by oxidation of circulating lipids. This rationale popularized supplementation of at-risk patients with vitamin E in the 1980s and 1990s as a preventive measure against CHD. Since clinical trials failed to demonstrate a significant benefit for supplementation with vitamin E, α -tocopherol is no longer considered an effective treatment for CHD patients.

Cancer

Since elevation in markers of oxidative stress is seen in many malignant diseases, vitamin E sufficiency is thought to have an important chemopreventive value. In support of this notion, supplementation with vitamin E was shown to bring about profound clinical improvement in genetic animal models of

cancer (e.g., hepatocellular carcinoma and prostate cancer). However, clinical trials to date have not provided consistent support for this claim.

Fertility

Despite the original description of vitamin E as a fertility factor in rodents, the relevance of α -tocopherol to human reproduction has not been determined.

A Vitamin E Paradox?

One of the most intriguing features of vitamin E is its cyclic emergence and disappearance from research texts and pharmacopeias as an effective agent in the treatment of human disease. These oscillations in the biomedical community likely reflect conflicting published reports regarding the vitamin's health-promoting value in different experimental settings. On the one hand, laboratory studies repeatedly demonstrated that tocopherol elicits clear protective actions in isolated cells, tissues, and animal models. On the other hand, controlled intervention trials assessing clinical outcomes in humans provided inconsistent results at best. These seemingly contradicting observations gave rise to general confusion regarding the actual therapeutic value of vitamin E adequacy and supplementation. A clue to this apparent paradox may be found in observations indicating that vitamin E status is a stable individual phenotype under genetic control. Thus, it is possible and even likely that individual differences (such as single-nucleotide polymorphisms) in the genes that regulate vitamin E status may determine the individual biochemical and clinical responsiveness to vitamin E. Future investigations into the interrelations between individual genotype, vitamin E status, and disease risk may provide critical tools that may facilitate reevaluating clinical trial data and obtaining important insight into this apparent paradox.

Dietary Sources and Recommended Intake of Vitamin E

Vitamin E is ubiquitous in foods of both plant and animal origin. Food sources with the highest vitamin E concentrations are the seed (vegetable) oils, in which tocopherols and occasionally tocotrienols are extensively deposited presumably to prevent autooxidation of polyunsaturated lipids. However, vegetable oils differ markedly in the type of vitamin E deposited, with some containing mostly α -tocopherol (such as sunflower with ~95% α -tocopherol and 5% β -tocopherol) and others containing mostly other forms (such as soybean with ~13:3:62:22% of α : β : γ : δ -tocopherol, respectively). Interestingly, the oilseed palm and annatto grown in tropical regions are unique in that a large proportion of vitamin E exists as tocotrienols. Fats from animal origin such as butter and lard contain predominantly α -tocopherol due to the selective accumulation of that form of vitamin E. Thus, the amount and types of oils consumed by an individual determine their intake of different vitamin E forms. While fruits and vegetables contain much lower concentrations of vitamin E than lipid-rich products, some, such as tomatoes and tomato products, are major dietary sources due to the prevalence of their

consumption. The 2000 edition of the Dietary Reference Intakes (IOM) summarized data suggesting that most adults in the US and Canada probably consume the Dietary Reference Intakes (DRI) for vitamin E, that is, the equivalent of 15 mg RRR- α -tocopherol per day, but this value will vary widely with fat intake and persons on fat-restricted diets likely consume significantly less than the DRI.

The latest US governmental recommendations regarding vitamin E were published in 2000 by the Food and Nutrition Board convened by the Institute of Medicine of the National Institutes of Health. As in the past, the panel relied almost exclusively upon the *ex vivo* data of Horwitt and co-workers from the early 1960s involving hydrogen peroxide-induced hemolysis of red blood cells obtained from vitamin E-deficient men before and after repletion with varying amounts of α -tocopherol. The 2000 panel re-interpreted the data to conclude that 12 mg of RRR- α -tocopherol per day was required to yield a plasma concentration ($12 \mu\text{mol l}^{-1}$) sufficient to prevent *in vitro* red blood cell (RBC) hemolysis under the test conditions employed, and therefore the estimated average requirement (EAR) was considered as 12 mg RRR- α -tocopherol per day. This value was increased by the customary two standard deviations (assumed to be 10%) to yield the current recommended dietary allowance (RDA) of 15 mg d^{-1} for adults. No differences are associated with gender or pregnancy, but the RDA for lactating women was set at 19 mg d^{-1} due to losses of vitamin E in breast milk. These RDA values generally represent an increase of 3 mg d^{-1} over the previous set of recommendations. A second deviation from the previous recommendations was that forms of vitamin E other than α -tocopherol (e.g., γ -tocopherol) were to be disregarded in terms of meeting the recommended dietary allowance; previous editions considered γ -tocopherol as one-tenth as bioactive as α -tocopherol.

The relationship between α -tocopherol intake and plasma α -tocopherol concentration is linear within the range of intakes possible from average diet ($0\text{--}17 \text{ mg d}^{-1}$). At higher intakes, using supplements, this relationship becomes severely nonlinear such that a doubling of plasma concentration from 25 to $50 \mu\text{mol l}^{-1}$ requires increasing intake by at least 10-fold, and concentrations much above $60 \mu\text{mol l}^{-1}$ are not possible even with doses near 1 g d^{-1} . The reasons for this nonlinearity are not known, but are likely to involve multiple phenomena.

The natural (RRR) and synthetic (racemic mixture) forms of α -tocopherol exhibit different bioavailabilities in animals and humans. The synthetic form is 70% as active in the rat gestation-resorption assay. A similar difference is seen in humans comparing their pharmacokinetics in plasma following single doses administered separately, that is, under non-competitive conditions. The difference is attributed to the higher affinity of RRR- α -tocopherol to the liver tocopherol transfer protein, such that this form is more efficiently secreted by the liver into the bloodstream.

The current upper limit (UL) for vitamin E intake was set by the US Institute of Medicine panel at $1000 \text{ mg } \alpha$ -tocopherol per day for adults, a sum of natural and synthetic forms. Establishment of this value was based on several factors, including evidence of hemorrhagic effects seen in some clinical trials involving vitamin E supplementation. However, while the human observations were seen as evidence for concern, the data quality was insufficiently quantitative for derivation of

a UL. Therefore, the UL was based on studies of hemorrhagic effects in rats, from which a lowest observed adverse effect level (LOAEF) of $500 \text{ mg per kg body weight per day}$ was determined. An uncertainty factor, consisting of several subfactors including extrapolation from animal to human, was estimated at 36, and the ULL of $14 \text{ mg kg}^{-1} \text{ d}^{-1}$ (1000 mg d^{-1} for adults) was obtained by dividing the LOAEF by the uncertainty factor. The mechanism by which high doses of vitamin E interferes with blood clotting remains unknown.

Transport of Vitamin E (DM)

Absorption

Like most dietary lipids, tocopherols are micellized in the intestinal lumen prior to uptake by intestinal epithelial cells. In the enterocyte, the microsomal triglyceride transfer protein (MTTP) facilitates the incorporation of vitamin E into apoB48-containing chylomicra, which are secreted into the lymph. Recent studies indicate the presence of an additional secretion route, involving active transport through an ABC-family transporter to high-density lipoprotein (HDL) particles. In these early absorptive stages (within $\sim 2 \text{ h}$ after ingestion), all members of the vitamin E family are handled with similar efficiency, such that relative composition of the different vitamin E species in chylomicra mirrors the dietary composition.

Hepatic Processing

The liver serves as the primary site for regulation of body-wide levels and content of vitamin E. Following uptake of chylomicra remnants by parenchymal cells in the liver, the hepatic TTP targets vitamin E to a specific secretory pathway out of the hepatocyte. Secretion of vitamin E from hepatocytes occurs through a unique pathway, independent from the route for assembly and secretion of nascent very low density lipoproteins (VLDLs). Furthermore, secretion from the hepatocytes takes place through an adenosine triphosphate (ATP)-driven system, including the ABCA1 transporter that is defective in Tangier disease patients. Following secretion, the vitamin associates with VLDL particles, which deliver it to extrahepatic tissues. The structure of TTP's ligand-binding pocket dictates a high degree of selectivity, such that the protein binds α -tocopherol at a significantly higher affinity compared to other members of the vitamin E family. TTP's ligand preference, together with the selective degradation of non- α vitamers by CYP4F2 (see below), comprise a remarkably efficient discriminatory system that results in the selective enrichment of human tissues with α -tocopherol.

Circulation and Delivery

In circulation, α -tocopherol is exclusively associated with lipoprotein particles. The plasma phospholipid transfer protein (PLTP) plays an important role in the exchange of vitamin E between HDL and LDL, such that in steady state the vitamin is distributed between these two particle populations. Uptake of α -tocopherol into extrahepatic cells is mediated by a number of parallel, possibly overlapping routes, including receptor-mediated endocytosis through the LDL receptor and uptake

from HDL through the scavenger receptor SR-BI. In addition, endothelial lipoprotein lipase mediates direct exchange of α -tocopherol between lipoprotein particles and the surface of target cells.

The profound hydrophobicity of α -tocopherol (calculated $\log P \sim 9$) raises the attractive hypothesis that specific transport proteins are needed for adequate intracellular distribution of the vitamin in peripheral tissues. An α -tocopherol-binding activity was purified from heart tissue of several species, but the protein has not been identified or cloned. Thus, to date, the presence of an intracellular tocopherol binding in extrahepatic tissues is yet to be determined. The exception is the tocopherol transfer protein, which in addition to liver, is expressed in the brain and the uterus. The modes of action and physiological consequences of TTP's presence in these tissues await future examinations. It is tempting to speculate, however, that brain-TTP is responsible for the efficient enrichment of the central nervous system with tocopherol, and for the remarkable resistance of this tissue to dietary depletion.

Metabolism of Vitamin E

At the present time, there is only one known pathway of metabolism of vitamin E. This pathway, termed the tocopherol- ω -hydroxylase pathway, is initiated by an oxidation (hydroxylation) of one of the two terminal methyl groups of the hydrophobic side chain of tocopherols and tocotrienols (Figure 3). This reaction is catalyzed in the human by

Figure 3 The ω -hydroxylase pathway of vitamin E metabolism, illustrated with γ -tocopherol as substrate. The first step is catalyzed by cytochrome P450 4F2 (CYP4F2), requiring NADPH as electron donor. The final product is the 3'-carboxychromanol, which is excreted in the urine as its glucuronide conjugate. The same pathway is responsible for metabolism of both tocopherols and tocotrienols.

cytochrome P450 4F2, and takes place predominantly in the endoplasmic reticulum of the liver. To date, no other enzymes exhibiting vitamin E ω -hydroxylase activity have been identified. The hydroxylated vitamin E then undergoes a second oxidation to the corresponding ω -carboxylated form by an as-yet unidentified microsomal dehydrogenase. The oxidized side chain then undergoes a series of two- or three-carbon truncations analogous to the oxidation of branched-chain fatty acids, ultimately yielding the 3'- and 5'-carboxychromanol metabolites that are excreted in the urine. Despite the considerable water solubility of these metabolites, they are excreted largely, if not entirely, as glucuronide conjugates. Both conjugated and nonconjugated 3'- and 5'-carboxychromanol metabolites circulate in the bloodstream, suggesting that additional conjugation may take place in the kidney. The site of glucuronidation appears to be the phenol hydroxyl group, meaning that such metabolites do not have antioxidant activity in their conjugated state.

The ω -hydroxylation pathway is of significance due to the remarkable substrate preference for vitamin E forms other than α -tocopherol. α -Tocopherol is metabolized 3–15-fold slower than other tocopherols. Natural and synthetic α -tocopherol are metabolized at similarly low rates. Additionally, tocotrienols are metabolized more rapidly (2–20-fold) than the corresponding tocopherols. Since absorption of the various forms of vitamin E is similar, it is likely that this pattern of substrate discrimination exhibited by CYP4F2 plays an important role in the highly selective tissue accumulation of α -tocopherol, observed in essentially all complex organisms. An additional contribution to this selectivity is made by the hepatic TTP, which selectively destines α -tocopherol for secretion from the liver into the bloodstream. Both TTP and ω -hydroxylase underlie the remarkable difference between the vitamin E composition of the diet, which can favor γ -tocopherol over α -tocopherol by 4:1, and that in human blood and tissues, in which the same ratio is typically about 1:15.

Tocopherol quinones are thought to be generated at slow rates during the antioxidant action of vitamin E. Although the glucuronide conjugate of the 3'-carboxychromanol metabolite of α -tocopherol quinone has been identified in urine, the extent to which its presence reflects artifactual oxidation during analysis versus actual side chain truncation of α -tocopherol quinone *in vivo* remains unclear.

Expression of the tocopherol/tocotrienol- ω -oxidation pathway appears widespread in the animal kingdom, including the fruit fly, *Drosophila melanogaster*. As *Drosophila* does not have a sequence ortholog of cytochrome P450 4F2, another P450 enzyme apparently exists in this species that promotes the selective accumulation of α -tocopherol. Interestingly, the *D. melanogaster* genome does not encode a tocopherol transfer protein ortholog, suggesting that the selective accumulation of α -tocopherol exhibited by this species arose prior to the evolution of TTP, whose function appears to be vitamin E retention. The selective pressure(s) underlying the evolution of the hydroxylase and TTP, and their persistence throughout the animal kingdom, remain a mystery. There are two relatively common nonsynonymous single-nucleotide polymorphisms in the human cytochrome P450 4F2 gene, but their effects on vitamin E status have not yet been determined.

Glossary

γ -Carboxyglutamic acid An amino acid found in a limited number of proteins, formed by a posttranslational modification of Glu residues.

γ -Glutamyl carboxylase The enzyme involved in the formation of Gla residues; also called vitamin K-dependent carboxylase.

Vitamin K-Dependent Proteins

Prothrombin (clotting factor II), the zymogen of the plasma procoagulant thrombin, was the first protein shown to be dependent on vitamin K for its synthesis, and was also the first protein demonstrated to contain γ -carboxyglutamyl (Gla) residues. Plasma clotting factors VII, IX, and X were all initially identified in patients with hereditary bleeding disorders and were subsequently shown to be vitamin K dependent. Until the mid-1970s, these four vitamin K-dependent clotting factors were the only proteins known to require this vitamin for their synthesis. The amino-terminal, Gla domains of these four vitamin K-dependent procoagulants are very homologous, and the 10–13 Gla residues in each are in essentially the same position as in prothrombin.

Following the discovery of Gla, three more Gla-containing plasma proteins with similar homology were discovered. Protein C and protein S are involved in an anticoagulant rather than a procoagulant role in normal hemostasis, and the seventh Gla-containing plasma protein (protein Z) also has an anticoagulant function under some conditions. As these proteins play a crucial role in hemostasis, they have been extensively studied, and the complementary DNA (cDNA) and genomic organization of each of them are well documented.

The discovery of Gla residues in the plasma vitamin K-dependent proteins led to a search for other proteins with this modification, and a 49-residue protein that contained three Gla residues, called osteocalcin (OC), was isolated from bone. It has little structural homology to the vitamin K-dependent plasma proteins. Although it is the second-most-abundant protein in bone, its function is not clearly defined. A second low-molecular-weight (79-residue) protein, matrix Gla protein (MGP), contains five Gla residues and was also first isolated from bone; it is also synthesized in cartilage and many other soft tissues. The function of these two proteins has not been clearly defined, but it has been shown that OC gene knockout mice develop more dense bones, and MGP knockout mice die from spontaneous calcification of arteries and cartilage. Two additional Gla-containing bone proteins, periostin and Gla-rich protein, have been more recently identified. A limited number of other mammalian proteins have been found to contain Gla residues: Gas 6, a ligand for the tyrosine kinase Ax1, and four integral membrane Gla proteins (PRGP-1, PRGP-2, TMG-3, and TMG-4). A large number of Gla-containing toxic venom peptides are secreted by marine *Conus* snails and are found in some snake venoms. The vitamin

K-dependent carboxylase has been cloned from a number of vertebrates, the *Conus* snail, a tunicate, and *Drosophila*, indicating the ancient evolutionary origin of this posttranslational modification.

Biochemical Role of Vitamin K

In the early 1960s, a biologically inactive form of prothrombin was demonstrated to be present in the plasma of patients treated with oral anticoagulants. Subsequent studies with hypoprothrombinemic rats were consistent with the presence of a hepatic precursor protein pool that was rapidly being synthesized and which could be converted to prothrombin by a posttranslational modification. Characterization of the abnormal prothrombin isolated from the plasma of cows fed with the anticoagulant dicoumarol led directly to an understanding of the metabolic role of vitamin K. This protein lacked the specific calcium-binding sites present in normal prothrombin. Acidic peptides obtained by proteolytic enzyme digestion of prothrombin were shown to contain Gla residues, but Gla residues could not be obtained by proteolysis of the abnormal prothrombin.

The Vitamin K-Dependent Carboxylase

In 1975, it was demonstrated that crude rat liver microsomal preparation contained an enzymatic activity (the vitamin K-dependent carboxylase) that promoted a vitamin K-dependent incorporation of $\text{H}^{14}\text{CO}_3^-$ into Gla residues of endogenous precursors of vitamin K-dependent proteins present in these preparations. Detergent-solubilized microsomal preparations retained this activity, and small peptides containing adjacent Glu–Glu sequences were found to be substrates for the enzyme. A general understanding of the properties of this unique enzyme was gained from studies utilizing this crude enzyme preparation, and these data have been adequately reviewed. The vitamin K-dependent carboxylation reaction does not require adenosine triphosphate, and the energy to drive this carboxylation reaction is derived from the oxidation of the reduced, hydronaphthoquinone form of vitamin K (vitamin KH_2) by O_2 to form vitamin K-2,3-epoxide (Figure 1). The lack of a requirement for biotin and studies of the $\text{CO}_2/\text{HCO}_3^-$ requirement indicate that carbon dioxide rather than HCO_3^- is the active species in the carboxylation reaction. Active substrates for the enzyme are 2-methyl-1,4-naphthoquinones

Figure 1 The vitamin K-dependent, γ -glutamyl carboxylase. The available data support an interaction of O₂ with vitamin KH₂, the reduced (hydronaphthoquinone) form of vitamin K, to form an oxygenated intermediate which is sufficiently basic to abstract the γ -hydrogen of the glutamyl residue. The products of this reaction are vitamin K-2,3-epoxide and a glutamyl carbanion. Attack of CO₂ on the carbanion leads to the formation of a Gla residue. The bracketed peroxy, dioxetane, and alkoxide intermediates have not been identified in the enzyme-catalyzed reaction but are postulated based on model organic reactions, and the available data are consistent with their presence.

Figure 2 Structures of vitamin K active compounds. Phylloquinone (vitamin K₁) synthesized in plants is the main dietary form of vitamin K. Menaquinone-9 is a prominent member of a series of menaquinones (vitamin K₂) produced by intestinal bacteria, and menadione, vitamin K₃, is a synthetic compound that can be converted to menaquinone-4 by animal tissues.

substituted at the 3-position with a rather hydrophobic group. Although some differences in biological activity can be measured, phylloquinone, the plant form of the vitamin, and the predominant bacterial menaquinones are all effective substrates (Figure 2).

Only a small fraction of the proteins secreted by the liver to the plasma is vitamin K dependent, so an efficient mechanism for recognizing the precursors of the vitamin K-dependent proteins is essential. The primary gene products of the vitamin

K-dependent proteins contain a very homologous domain between the amino terminus of the mature protein and the signal sequence. This propeptide region appears to be both a docking or recognition site for the enzyme and a modulator of the activity of the enzyme by decreasing the apparent K_m of the Glu site substrate. The role of vitamin K in the overall reaction catalyzed by the enzyme is to abstract the hydrogen on the γ -carbon of the glutamyl residue to allow attack of CO₂ at this position. A number of studies that utilized substrates

tritiated at the γ -carbon of each Glu residue have been used to define the action and stoichiometry involved and have shown that it was an apparent equivalent stoichiometry between vitamin K-2,3-epoxide formation and Gla formation. The mechanism by which epoxide formation is coupled to γ -hydrogen abstraction is key to a complete understanding of the role of vitamin K. The association between epoxide formation, Gla formation, and γ -C-H bond cleavage has been studied; the reaction efficiency defined as the ratio of Gla residues formed to γ -C-H bonds cleaved has been shown to be independent of Glu substrate concentrations, and to approach unity at high CO_2 concentrations. Identification of an intermediate chemical form of vitamin K, which could be sufficiently basic to abstract the γ -hydrogen of the glutamyl residue, has been a challenge. A possible candidate is the one first proposed by Dowd, who suggested that an initial attack of O_2 at the naphthoquinone carbonyl carbon adjacent to the methyl group results in the formation of a dioxetane ring that generates an alkoxide intermediate. This intermediate is hypothesized to be the strong base that abstracts the γ -methylene hydrogen and leaves a carbanion that can interact with CO_2 . This pathway leads to the possibility that a second atom of molecular oxygen can be incorporated into the carbonyl group of the epoxide product as well as the epoxide oxygen, and this partial dioxygenase activity has been demonstrated. Although the general scheme shown in Figure 1 is consistent with all of

the available data, the mechanism remains a hypothesis at this time.

Progress in purifying this enzyme was slow. Utilization of bound propeptide as an affinity column aided progress in this field, and the enzyme was eventually purified to near homogeneity and cloned. The carboxylase is a unique 758-amino-acid residue protein with a sequence suggestive of an integral membrane protein with a number of membrane-spanning domains in the N terminus, and a C-terminal domain located in the lumen of the endoplasmic reticulum. It has been demonstrated that the multiple Glu sites on the substrate for this enzyme are carboxylated processively as they are bound to the enzyme via their propeptide, while the Gla domain undergoes intramolecular movement to reposition each Glu for catalysis, and that release of the carboxylated substrate is the rate-limiting step in the reaction.

Metabolic Interconversion of Vitamin K

Gla residues are not metabolized but are excreted in the urine. The amount of Gla excreted by an adult human is in the range of $50 \mu\text{mol d}^{-1}$, so a similar amount must be formed each day. As the dietary requirement of vitamin K is only $\sim 0.2 \mu\text{mol d}^{-1}$, and tissue stores are very low, it is clear that the vitamin K 2,3-epoxide generated by the carboxylase can be actively recycled by the pathway shown in Figure 3. The vitamin

Figure 3 Tissue metabolism of vitamin K. Vitamin K epoxide formed in the carboxylation reaction is reduced to the quinone form of the vitamin by a warfarin-sensitive pathway, vitamin K epoxide reductase, that is driven by a reduced dithiol. The naphthoquinone form of the vitamin can be reduced to the hydronaphthoquinone form either by the same warfarin-sensitive dithiol-driven reductase or by one or more of the hepatic NADH or NADPH-lined quinone reductases which are less sensitive to warfarin.

K-epoxide reductase is capable of reducing both the epoxide to the naphthoquinone and naphthoquinone to the hydro-naphthoquinone, and this is the enzyme which is blocked by the common oral anticoagulant warfarin. In addition to the epoxide reductase, the quinone and hydronaphthoquinone forms of the vitamin can also be interconverted by a number of reduced form of nicotinamide adenine dinucleotide phosphate (NAD(P)H)-linked reductases including one that appears to be a microsomal-bound form of the extensively studied liver DT-diaphorase activity. The epoxide reductase utilizes a sulfhydryl compound as a reductant *in vitro*, but the physiological reductant has not been identified.

A second metabolic pathway utilizing phyloquinone has been discovered more recently. A number of extrahepatic tissues such as brain, salivary gland, and pancreas of rats and humans fed with phyloquinone have been found to contain a much higher concentration of menatetrenone (MK-4) than of phyloquinone. Tissue formation of MK-4 from phyloquinone fed to germ-free rats and the observation that cultured kidney cells can convert phyloquinone to MK-4 have now demonstrated that bacterial action is not involved in the conversion and that numerous cell types have the ability to carry out this transformation. Details of the mechanism of this conversion are lacking, but it seems unlikely that a metabolic pathway leading to MK-4 has evolved unless there is some specific role for this vitamin. This role is unlikely to involve the vitamin K-dependent carboxylase, as phyloquinone and MK-4 have similar activity as a substrate for this enzymatic activity, and is more likely to act as a ligand for various receptors regulating metabolism.

Nutritional Aspects of Vitamin K

Reports of uncomplicated adult deficiencies of vitamin K are extremely rare, and most diets contain an adequate amount ($\sim 100 \mu\text{g d}^{-1}$) of vitamin K. Low lipid intake or the impaired lipid absorption resulting from the lack of bile salts will adversely affect vitamin K absorption, and depression of the vitamin K-dependent coagulation factors has frequently been

reported in various malabsorption syndromes. This classic example of a human vitamin K deficiency is that of early vitamin K deficiency bleeding occurring during the first week of life in healthy-appearing neonates. Low placental transfer of phyloquinone, low clotting factor levels, a sterile gut, and the low vitamin K content of breast milk all contribute to the disease. Although the incidence is low, the mortality rate from intracranial bleeding is high, and prevention by oral or parenteral administration of vitamin K immediately following birth is the standard cure. The presence of large amounts of OC in bone and reports that low vitamin K intake or increased amounts of circulating under- γ -carboxylated OC are correlated with low bone mineral density or fracture rate have focused significant attention on a possible role for vitamin K in bone health. A number of controlled studies of phyloquinone supplementation have, however, failed to demonstrate that additional intake of the vitamin will decrease bone fracture rate or increase bone mineral density. MGP, which has been shown to present ectopic calcification in animal models, is also being studied to determine if it plays a role in controlling cardiovascular disease.

Glossary

Delayed rectifier A K⁺ channel that changes the membrane conductance with a delay after a depolarizing voltage step.

Gating The opening or closing of a channel in response to some stimulus.

Inward rectifier A K⁺ channel that opens when the membrane is hyperpolarized.

Long QT syndrome An inherited cardiac arrhythmia.

Missense mutation A mutation in which an incorrect amino acid is incorporated into the protein.

Voltage sensor A channel structure able to detect changes in membrane potential. In voltage-dependent ion channels, the voltage-sensing elements are located in the S4 segment.

Structure and Diversity

Voltage-dependent K⁺ channels are members of the voltage-dependent cation channel family, which includes the voltage-dependent Na⁺, Ca²⁺, and K⁺ channels. The first voltage-dependent K⁺ channel was cloned in 1987 from a fruit fly, *Drosophila*, based on a mutation that causes the *Shaker* phenotype. After that, they have been identified in an immense number of organisms including prokaryotes and eukaryotes.

The 78 members of the K⁺ channel superfamily can be divided into four structural types based on their mode of activation and the number of their transmembrane segments: (1) voltage-gated six-transmembrane K⁺ channels (K_v), (2) voltage- and Ca²⁺-activated seven-transmembrane K⁺ channels (K_{Ca}), (3) Inward rectifying two-transmembrane K⁺ channels (K_{ir}), and (4) two-pore four-transmembrane K⁺ channels (K_{2P}). Only the K_v and K_{Ca} families have channel-forming proteins containing intrinsic voltage sensors (see below).

All the voltage-dependent K⁺ channels are tetrameric assemblies. In the K_v channels, each subunit consists of six hydrophobic segments, S1–S6. The primary sequence of these hydrophobic segments shows similarities between all of the K_v channels, including the voltage-sensor domain (VSD, S1–S4) and the ion-conduction pore domain (S5–S6) (**Figure 1(a)**).

All K⁺ channels have a consensus amino acid sequence inside the pore region, TVGYGD, dubbed the ‘signature sequence’. The residues, TVGYG, line the selectivity filter (in some K⁺ channels, the tyrosine (Y) residue is replaced by phenylalanine (F), e.g., in the ether-a-go-go (eag) channel discussed later on). In the selectivity filter, carbonyl oxygen atoms are directed toward the pore to coordinate dehydrated K⁺ ions. Hydrophobic chains of valine and tyrosine directed toward the hydrophobic core surrounding the filter stabilize the main chain.

Gating in the K_v channels is conferred through the attachment of gating domains to the pore. The basic function of these gating domains is to perform mechanical work on the ion-conduction pore to change its conformation between closed

and opened states. In voltage-dependent channels, a VSD (S1–S4) is present on each subunit. Thus, a voltage sensor converts energy stored in the membrane electric field into mechanical work. There is strong evidence that the positive charges contained in S4 are the voltage-sensing elements. Thus, ion-channel gating is essentially an electromechanical coupling between a gating unit and a pore unit.

The crystal structure of a mammalian voltage-dependent K⁺ channel (K_v1.2) had initially been resolved at 2.9 Å and further improved to 2.4 Å using a chimeric K_v1.2–K_v2.1 channel. In the latter case, the channel was crystallized in complex with lipids. These structures showed that the helices of the ion-conduction pore (S5–S6) related to the helices of the VSD (S1–S4) in a special way. The VSD of one subunit is located near the pore domain of an adjacent subunit (**Figure 1(b)**). The connection between the pore and the VSD is made by the S4–S5 linker helix, which runs parallel to the intracellular membrane surface.

Voltage-dependent K⁺ channels are ubiquitously distributed in different cells and tissues, therefore, K⁺ channel diversity is of great importance in determining the variety of electrical responses produced by cells when subjected to stimuli. The possible mechanisms that originate the immense voltage-dependent K⁺ channel diversity are: (1) multiple genes; (2) alternative splicing; (3) formation of heteromultimeric channels; and (4) coexpression with regulatory β-subunits.

Voltage-dependent K⁺ channel diversity seems to have accompanied animal cells through evolution. Some K⁺ channels are the most conserved proteins in eukaryotes. Potassium channels became fundamental to animal cell physiology very early in evolution, and through voltage-dependent K⁺ channel control of membrane potential they couple the cell inner dynamics to the outer environment. A differential expression of voltage-dependent K⁺ channel messenger RNAs (mRNAs) is found to accompany the events of animal development and also occurs in adult animal tissues.

The diversity of voltage-dependent K⁺ channel genes is shown in the dendrogram shown in **Figure 2**. The dendrogram shows the major classes of voltage-dependent K⁺ channels. The ramification of voltage-dependent K⁺ channels was

Figure 1 Structural characteristics of voltage-dependent potassium channels. (a) The figure in the center shows a six-transmembrane segment secondary structure of an archetypical voltage-dependent potassium channel. Cylinders represent α -helix domains crossing the bilayer connected by loops. The voltage-sensor domain (VSD) is defined as the structure composed of S1–S4 (red cylinders). The channel pore consists of segment S5 and S6 and a short α -helix denominated the pore helix (P-helix) (blue cylinders). The sequence GYGD is located in the loop that connects the P-helix with S6. The functional channel is a tetramer (left) and the voltage sensor and the channel pore are depicted in the tetramer in the right figure. (b) Crystal structure of the chimerical channel $K_v1.2$ – $K_v2.1$ (access number 2R9R). The left side of the figure shows an amplification of the transmembrane segments S4 (ribbon in red) belonging to the subunit labeled as 1, and S5 (ribbon in yellow) belonging to the contiguous subunit, labeled as 2, showing that in the quaternary structure these segments are spatially related. The central figure shows the lateral structure of the channel. Part of the channel structure has been removed in order to leave the conduction pathway exposed. Four K⁺ ions (purple spheres) are shown coordinated by sites in the selectivity filter. A 90° rotation of the structure shown in the central figure allows us to appreciate the external aspect of the channel.

constructed by carrying out sequence alignments. To compare the amino acid sequences of the different voltage-dependent K⁺ channels, the sequences were aligned using at least 300 amino acids from six hydrophobic segment (S1–S6) channels and their respective linkers. Branch lengths do not correspond to time; however, branching is expected to preserve evolutionary relationships.

Physiological Function

Voltage-Gated Six-Transmembrane K⁺ Channels

The vertebrate fast voltage-gated K⁺ delayed rectifier or, K_v channels, fall into a variety of families (K_v1 – K_v12) according to their amino acid sequence similarity (Figure 2). A channel from the fruit fly *Drosophila* was the first K⁺ channel to be cloned (*Shaker* and denominated in vertebrates as $K_v1.1$, the first number denoting subfamily and the second, order of discovery). The identification started with mutant flies called shakers, which shake their legs while under ether anesthesia. These flies lack a fast-transient K⁺ current in presynaptic terminals, so repolarization of the action potential is delayed and the release of neurotransmitter from a single action potential becomes enormous.

K_v channels are found in a wide range of different tissues and have many different functions. For example, $K_v3.1$ channels are found in some neurons that are specialized to fire very short action potentials at high rates, such as those of the auditory system; $K_v1.3$ channels found in leukocytes play a role in inflammatory response; $K_v1.2$ channels are found in smooth muscle and participate in contractile tone regulation; and $K_v4.2$ channels expressed in myocardium prolong cardiac action potential.

The K_v7 subfamily is also known as KCNQ channels. The first member of the KCNQ subfamily to be cloned, *KCNQ1* ($K_v7.1$), was isolated because mutations in this gene give rise to the most common form of long QT syndrome, LQT1. *KCNQ1* encodes the major subunit of the cardiac I_{Ks} channel, which is involved in the repolarization of ventricular action potential. *KCNQ1* mRNA is expressed strongly in the heart, with lower levels in the pancreas, kidney, lung, placenta, and ear. Exploiting their homology to *KCNQ1*, other members of the K_v7 subfamily were subsequently cloned. It has been suggested that *KCNQ2* ($K_v7.2$) and *KCNQ3* ($K_v7.3$) form a heteromer, an idea which is consistent with their overlapping tissue distribution and studies where antibodies directed against *KCNQ2* are able to coimmunoprecipitate *KCNQ3* and vice versa. The heteromeric *KCNQ2/KCNQ3* channel corresponds to the

M-channel found in neurons. They are widely distributed throughout the brain and sympathetic and dorsal root ganglia, and expressed at high levels in hippocampus, chordate nucleus, and amygdala. KCNQ4 (K_v7.4) is expressed in outer hair cells and neurons of the auditory system and vascular smooth muscle. K_v5, K_v6, K_v8, and K_v9 channels are not functional alone; they coassemble with K_v2 subunits and modify their function.

Defects in K_v channels' function may have profound physiological effects. Linkage studies have identified the gene responsible for episodic ataxia type-1. This gene KCNA1 encodes the K_v1.1 channel, which is expressed in synaptic terminals and dendrites in brain neurons. Moreover, a variant in the promoter of the gene KCNA3 (encoded for K_v1.3 channel) is associated with impaired glucose tolerance and lower insulin sensitivity. A missense mutation in the gene KCNC3 (K_v3.3) causes spinocerebellar ataxia 13. Mutations in KCNQ2 and KCNQ3 give rise to a form of idiopathic epilepsy known as benign familial neonatal convulsions. Loss-of-function mutations in KCNQ4 cause deafness autosomal-dominant 2a.

Another important subgroup of K_v channels was first cloned in mutant fruit flies, which shook their legs like they

were 'go-go dancing' when anesthetized with ether. These flies were carriers of a mutated gene for a voltage-gated K⁺ known as *eag*. A family of *eag*-like genes was isolated from *Drosophila*, known as *eag*, *erg*, and *elk*. The human *eag*-related gene (human ether-a-go-go-related gene (HERG) or K_v11.1) was cloned from a human hippocampal complementary DNA library. HERG was strongly expressed in the heart. LQT2, a mutation on this gene, impairs the repolarization of the cardiac action potential, causing a form of long QT syndrome. Pharmacological blocking of HERG K⁺ channels reduces I_{Kr} and can prolong ventricular repolarization. This is shown by a lengthening of QT interval on the surface electrocardiogram – QT prolongation is a well-known risk factor for the occurrence of ventricular tachycardia.

Plant K_v-Like Channels: Inward and Outward Rectifiers

Potassium is a major factor in resistance to drought, salinity, and fungal disease in plants, as plant cells utilize inorganic ions, especially K⁺, as major osmotically active solutes to drive changes in cell volume. Voltage-dependent inward K⁺ channels (K channel from *Arabidopsis thaliana* (KAT)1/2,

Figure 2 (Continued)

Figure 2 Major classes of voltage-dependent K⁺ channels and tissue localization. (a) Amino acid sequence alignments for the inward rectifier, K_{ir} family, the human KCa1/4/5 group family, and the voltage-gated K⁺ channels in plants were created using CLUSTALW. Analysis by maximum parsimony using PAUP* resulted in the above two first trees, the third one was created using Phylogeny.fr and PhyML 3.0. International Union of Pharmacology and HUGO Gene Nomenclature Committee names of the genes are shown together with their tissue localization in human, mouse, or rat organism for the two first trees. The *Arabidopsis* Information Resource (TAIR) was used for cataloging the genes of voltage-gated K⁺ channels in *Arabidopsis thaliana*. Tissue channel expression together with the corresponding gene is shown. The more similar the sequences for a pair of genes, the shorter the path connecting them. (b) Phylogenetic tree for the K_v1–K_v9 families and K_v10–K_v12: amino acid sequence alignments of the human channel K_v proteins were created using CLUSTALW, and analysis by maximum parsimony using PAUP* resulted in unrooted trees comprising the K_v1–K_v6 and K_v8–K_v9 families and K_v10–K_v12. Sequences of K_v7.1–K_v7.5, K_v6.4, and K_v8.2 were incorporated into the existing tree topology using a combination of maximum parsimony and neighbor-joining analysis. Only the hydrophobic cores (S1–S6) were used for the analysis. The IUPHAR and HGNC names are shown together with the localization in human, mouse, or rat organism. The more similar the sequences for a pair of genes, the shorter the path connecting them.

Arabidopsis thaliana K channel (AKT1/2/3) rectifiers mediate potassium uptake in plants. KAT1 and AKT1 were the first inward rectifier K⁺ channels cloned from the plant *Arabidopsis thaliana*. They are tetramers formed by subunits containing six transmembrane domains with a positively charged fourth (S4) transmembrane segment, such as *Shaker* channels. The KAT1

channel is expressed in guard cells where it regulates the aperture of the stomata and the vascular system of the stem. AKT1 is present in guard cells and in the root cortex and plays an important role in K⁺ uptake from the soil. Voltage-dependent outward rectifiers, on the other hand, are represented by guard cell outward rectifier K channel (GORK) and stomatal potassium

outward rectifier channel (SKOR), present in different tissues of the root. GORK is also present in guard cells regulating the stomata closing. SKOR is expressed within the xylem parenchyma of the root where it facilitates K⁺ loading into the xylem.

Voltage- and Ca²⁺-Activated Seven-Transmembrane K⁺ Channels

A change in the intracellular calcium concentration is a ubiquitous signaling mechanism that is frequently coupled with changes in membrane potential. These signals are integrated by the activation of a heterogeneous family of potassium channels, Ca²⁺-activated potassium channels (K_{Ca}), whose open probability is increased by the elevation of cytosolic calcium to cause membrane hyperpolarization. They are found in a wide range of different tissues and in virtually all multicellular organisms. In nerve cells, they play a key role in controlling the action potential waveform and in regulating cell excitability. In secretory epithelia, they are also involved in K⁺ secretion. K_{Ca} channels contribute to the repolarization and after-hyperpolarization of vertebrate neurons. As this article is related to a voltage-dependent K⁺ channel only, the importance of one K_{Ca} channel family code by a single gene called *slowpoke* (*slo*) is discussed in this section.

Expression of *Slo* in mammalian cells or *Xenopus* oocytes induces the appearance of a highly K⁺-selective, Ca²⁺-activated, and voltage-dependent channel also known as MaxiK or BK (big K) because of its large single-channel conductance (>200 pS in 100-mM symmetrical K⁺). In contrast to its other voltage-dependent K⁺ channel congeners, the *Slo* protein has an extra hydrophobic segment at the NH₂ terminus called S0. Thus, the NH₂ terminus of the protein is placed in the extracellular side of the membrane. The intracellular COOH-terminal comprises about two-thirds of the protein containing four hydrophobic segments, several alternative splicing sites, and a stretch of negatively charged amino acids (aspartates) dubbed the 'Ca²⁺ bowl'. The Ca²⁺ bowl has emerged as a good candidate for the high-affinity Ca²⁺-binding site. The cytoplasmic domain of each *Slo* 1 subunit can be divided into two separate structures, both with sequence homology to the regulatory domain for K⁺ conductance (RCK) domains and was proposed that *Slo*1 channels would also contain a gating ring formed by eight RCK domains from the four *Slo*1 subunits.

Slo channels control a large variety of physiological processes, including smooth muscle tone, neurosecretion, and hearing. Despite being coded by a single gene, the diversity of *Slo* channels is great. Regulatory β -subunits, splicing, and metabolic regulation create this diversity which is fundamental to the adequate function of many tissues. Except in heart myocytes, *Slo* channels are almost ubiquitously expressed

among mammalian tissues, and play a variety of roles. *Slo* channels serve as negative feedback regulators of membrane potential and intracellular calcium concentration, which are important in a number of physiological processes. In smooth muscle, local Ca²⁺ increases, called Ca²⁺ sparks, generate spontaneous transient outward currents, which are generated by *Slo* channels. This hyperpolarizes the membrane causing muscle relaxation. In chromaffin cells, *Slo* channels are important for rapid termination of the action potential. In the cochlea of turtles, frogs, and chicks, gradients of spliced *Slo* channels, and β -subunits through interplay with voltage-dependent Ca²⁺ channels, they are able to generate the different oscillatory responses in the hair cells.

In agreement with their physiological importance, malfunction of BK channels (α - or β -subunits) can lead to epilepsy, motor impairment, noise-induced hearing loss, hypertension, urinary incontinence, overactive urinary bladder, and asthma.

Glossary

apoCaM Ca^{2+} -free calmodulin.

Electrical activity Results from ion flow through channels in membranes.

Electrochemical gradient Driving force for ions due to differences in concentrations and electrical potentials across membranes.

G proteins Small intracellular proteins involved in signaling pathways.

Oligomeric proteins Composition of several protein subunits.

Protein kinases Enzymes that catalyze phosphate transfer from adenosine triphosphate (ATP) to proteins; protein kinases are activated by distinct second messengers.

Second messengers Intracellular molecules formed after receptor activation and involved in signaling (e.g., cyclic-adenosine monophosphate (AMP), diacylglycerol).

Signaling cascade Information transfer within a cell.

Ion channels are integral, pore-forming transmembrane proteins that serve to pass ions across biological membranes. The channels differ in their ion selectivity, that is, each type allows certain ion species to permeate through the open channel pore. Conformational changes of the proteins leading to openings or closings of the channels are called 'gating'. It is achieved either by binding of ligands to special sites at the channels (ligand-gated ion channels) or by changes in membrane potential (voltage-gated ion channels). Calcium (Ca^{2+}) channels are voltage gated and have a high selectivity for Ca^{2+} ions. Opening of these channels by membrane depolarization leads to an influx of Ca^{2+} into the cell. The resulting increase in the intracellular Ca^{2+} concentration initiates essential physiological functions, such as cardiac contraction, secretion of hormones and neurotransmitters, gene transcription, or repetitive electrical activity of neurons and the heart. Most of these functions result from binding of Ca^{2+} to specific intracellular proteins (e.g., calmodulin, troponin C, etc.) which subsequently mediate the Ca^{2+} -dependent cellular responses. The diversity of voltage-gated Ca^{2+} channels in surface membranes of different cells is important for initiation of specific signaling cascades within the cells. The various types of Ca^{2+} channels are encoded by different genes and show tissue-specific expression. They are targets for toxins and for drugs used for therapeutic purposes.

Molecular Properties

Structures

Voltage-gated Ca^{2+} channels are oligomeric protein complexes composed of the voltage-sensitive, pore-forming α_1 -subunits, together with auxiliary disulfide-linked $\alpha_2\delta$ -subunits and intracellular β -subunits (Figure 1). An additional transmembrane γ -subunit is associated with $\alpha_1\text{S}$ in skeletal muscles. The diversity of Ca^{2+} channel types not only results from different genes coding for the different channel subunits (10 for α_1 , 4 for $\alpha_2\delta$, and 4 for β), but also from multiple splice variants of the subunits. The α_1 -subunits consist of four homologous domains (I–IV), each being composed of six transmembrane α -helical segments (S1–S6). The N and C termini are located

intracellularly, and the domains are linked together by intracellular loops. In the folded structures of α_1 -subunits, hairpin loops between transmembrane segments S5 and S6 constitute the channel pore. Segment S4 contains highly conserved, positively charged amino acids that act as voltage-sensitive sensors during gating of the channels. The $\alpha_2\delta$ -subunits are involved in the regulation of the channels' gating properties (voltage-dependent inactivation) and, like $\alpha_2\delta$ -subunits, play a role in the functional expression of the channels in cell surface membranes.

Selectivity

Ca^{2+} channels are selective pathways for the movement of Ca^{2+} ions down their electrochemical gradient into the cell. The pore-forming structures of the channel contain four negatively charged glutamate residues, each being in a homologous position on the four domains. The resulting ring of negative charges facing the pore coordinates binding of an entering Ca^{2+} ion. A second Ca^{2+} ion that enters the channel reduces the binding affinity of the first one by electrostatic repulsion, thus kicking it off from its binding site and letting it move down its electrochemical gradient. Thus, the selectivity of the channel for Ca^{2+} is critically dependent on the correctly placed negative charges of glutamate in the pore.

Calmodulin Binding

Two forms of autoregulation, Ca^{2+} -dependent inactivation and facilitation of $\text{Ca}_v1.2$ channels (Table 1), involve calmodulin (CaM). The subunit $\alpha_1\text{C}$ of $\text{Ca}_v1.2$ contains a consensus CaM-binding isoleucine-glutamine (IQ)-motif in its cytoplasmic C-terminal tail. The IQ-motif consists of 12 amino acids. Extensive mutations within this sequence revealed structural determinants for the two opposing forms of channel regulation. Two short stretches of amino acids upstream of the IQ-motif seem to be sites for constitutive, Ca^{2+} -independent binding of apoCaM. The IQ-motif binds CaM only in the presence of Ca^{2+} . It represents the regulatory site for Ca^{2+} -dependent inactivation, while facilitation may require additional activation of Ca/CaMkinaseII.

Figure 1 Oligomeric subunit complex of voltage-gated Ca²⁺ channels. The subunit composition consists of the pore-forming α_1 -subunit with its four homologous domains, the intracellular β -subunit, and the disulfide-linked α_2 -subunit. The sites of interaction between the subunits are indicated by the squares. An extra γ -subunit is present in skeletal muscle $\text{Ca}_v1.1$ complex (inset). Kindly prepared by Dr. R. D. Zuehlke, Bern.

Table 1 Ca²⁺ channels

Channel types ^a	Pore-forming α -subunits ^b	Tissue distribution	Pharmacology (blockers)
HVA			
Ca _v 1.1 (L)	$\alpha_1\text{S}$	Skeletal muscle	DHPs
Ca _v 1.2	$\alpha_1\text{C}$	Heart, smooth muscle, CNS	
Ca _v 1.3	$\alpha_1\text{D}$	CNS, kidney, cochlea, glands	
Ca _v 1.4	$\alpha_1\text{F}$	Retina	
Ca _v 2.1 (P/Q)	$\alpha_1\text{A}$	CNS	ω -Agatoxin
Ca _v 2.2 (N)	$\alpha_1\text{B}$	CNS	ω -Conotoxin.GVIA
Ca _v 2.3 (R)	$\alpha_1\text{E}$	CNS, heart, glands	
LVA			
Ca _v 3.1 (T)	$\alpha_1\text{G}$	CNS, sinus node	Mibefradil
Ca _v 3.2	$\alpha_1\text{H}$	CNS, heart, kidney, liver	
Ca _v 3.3	$\alpha_1\text{I}$	CNS	

^aChannel types: HVA, high-voltage-activated channels; LVA, low-voltage-activated channels; letters in brackets refer to the nomenclature of currents carried through the different channel types.

^bPore-forming α_1 -subunits encoded by identified genes have multiple splice variants (not shown); CNS, central nervous system; DHPs, dihydropyridines.

Phosphorylation

Ca²⁺ channel function can be modulated by second messenger-activated protein kinases (PKs) such as cyclic adenosine monophosphate (AMP)-dependent PKA, diacylglycerol-dependent PKC, or Ca/calmodulin-dependent kinases. Although the exact molecular mechanisms of these modulatory pathways are not yet fully understood, they do depend on

phosphorylation by kinases of specific amino acid residues of the Ca²⁺ channel protein. Multiple intracellular sites of phosphorylation have been identified on α_2 - and β -subunits. However, which phosphorylation sites are necessary and sufficient for different forms of modulation of Ca²⁺ channel function by the various protein kinases has not been clearly resolved.

G Proteins

Ca²⁺ channels of the Ca_v2 family (Table 1) that are involved in neurotransmitter and hormone secretion are inhibited by G proteins. There is excellent evidence that the rapid inhibition of the channels results from direct binding of the $\beta\gamma$ -subunits of G proteins to an identified segment of the intracellular loop between domains I and II (Figure 1), but other sequences in the C and N termini of the α_2 -subunits may also be important. Rapid inhibition of the channels by this mechanism does not require formation of soluble intracellular messengers. The inhibition results from a membrane-delimited pathway leading to the release of the $\beta\gamma$ -subunit of the G-protein complex.

Ca²⁺-Currents

Physiology

Depolarization of cell membranes during excitation leads to spontaneous openings (activation) and closings (inactivation) of Ca²⁺ channels. At a given voltage, stochastic openings of multiple channels produce a considerable flow of Ca²⁺ ions into a cell and can thus be measured as an electrical current. The currents are recorded by electrophysiological methods, at a level of resolution where even the current through an individual channel can be measured (patch-clamp method). This allows detailed quantitative analyses of the kinetic properties

(gating) and selectivities of the channels. Currents through different types of Ca^{2+} channels have traditionally been classified as L-, P/Q-, N-, R-, and T-type (Table 1). This classification resulted from functional and pharmacological analyses before the channels were cloned and sequenced. A general overview of the distribution of the channels in different tissues is summarized in Table 1. The specific expression of different Ca^{2+} channel types in different tissues is of great physiological and pharmacological importance. The localization of individual channels in association with other cellular constituents governs specific signaling pathways. For example, P/Q- and N-type channels are directly linked to the soluble *N*-ethylmaleimide sensitive fusion protein attachment protein receptor (SNARE) protein complex in neural and endocrine cells that is essential for secretion of neurotransmitters and hormones. L-type channels that are predominant in cardiac cells are in close proximity to intracellular Ca^{2+} stores. When Ca^{2+} ions move through the channels into these cells during excitation, they release more Ca^{2+} from the stores which eventually leads to contraction of the heart. Thus, changes in the intracellular Ca^{2+} -concentration are coding for important information of diverse cellular functions. Auto-regulatory mechanisms, by which the channels inactivate in voltage- and Ca^{2+} -dependent manners, prevent Ca^{2+} overload of the cells. Ca^{2+} -dependent inactivation has been studied most extensively in L-type Ca^{2+} channels, but may also apply to other channel types. During the flow of Ca^{2+} ions through the pore, they bind to constitutively tethered apoCaM at the cytoplasmic C terminus of the channel. Occupancy of CaM by Ca^{2+} triggers binding of its C-terminal lobe to the nearby IQ-motif and accelerates inactivation of the

channel, possibly by disinhibiting voltage-dependent inactivation (Figure 2).

Modulation

Modulation of Ca^{2+} channel activity by neurotransmitters and hormones has become a major field of research. The upregulation of cardiac Ca^{2+} current ($\text{Ca}_v1.2$) by epinephrine was the first example of modulation of an ion channel by a neurotransmitter. It has been shown to be the result of activation of the cyclic AMP pathway via β_1 -adrenoceptors and subsequent phosphorylation by protein kinase A of amino acid (serine) residues at intracellular sites of the channel. This causes enhanced probability of openings of the channels, resulting in largely increased Ca^{2+} currents. Other examples of modulation mainly concern N- and P/Q-type Ca^{2+} channels ($\text{Ca}_v2.1$ and $\text{Ca}_v2.2$; Table 1). They are inhibited by neurotransmitters, such as norepinephrine. Release of G-protein $\beta\gamma$ -subunits by neurotransmitters shifts channel activation into a reluctant state, thus causing a reduction of Ca^{2+} currents during depolarization. These are just two examples of modulation of Ca^{2+} channel activities. There are several others that are not included under the scope of this article.

Pharmacology

Ca^{2+} channels are important targets for toxins and drugs. Although a full discussion of their effects is beyond the scope of this article, a few of them are listed in Table 1. Dihydropyridines (e.g., nifedipine and nimodipine) are relatively specific inhibitors of the Ca_v1 channel family, mainly $\text{Ca}_v1.2$ type.

Figure 2 Model of voltage- and Ca^{2+} -dependent gating of a Ca^{2+} channel. The model shows a schematic folding of the $\alpha 1$ -subunit in Figure 1. At membrane resting potential the pore is closed (resting state); upon depolarization (ΔV) the pore opens and Ca^{2+} ions move across the membrane down their electrochemical gradient (open state); when the intracellular Ca^{2+} -concentration increases, Ca^{2+} binds to tethered calmodulin (CaM) which then attaches itself to the regulatory IQ-motif and promotes closure of the pore (inactivated state). Kindly prepared by Dr. R. D. Zuehlke, Bern.

Other drugs acting on these channels are the phenylalkylamines verapamil and the benzothiazepine diltiazem. They are grouped together as Ca-channel blockers and are therapeutically used for the treatment of cardiovascular diseases, notably hypertension and angina pectoris. The toxins have no, or very limited, therapeutic use. In some cases of otherwise untreatable pain, the N-type channel blocker ω -conotoxin GVIA has been successfully applied. Because of unwanted side effects, the T-type channel blocker mibefradil has been withdrawn from therapeutic use, although it was quite effective in the treatment of essential hypertension.

Channelopathies

Diseases resulting from mutations of genes encoding calcium channels are beginning to be identified. Dominantly inherited night blindness seems to result from a mutation of the gene encoding the retinal Ca^{2+} channel $\alpha 1\text{F}$. Several neurological disorders (e.g., familial hemiplegic migraine and episodic ataxias) are associated with mutations in the $\alpha 1\text{A}$ gene. This field of research is rapidly evolving and will hopefully lead to better therapeutic possibilities.

Voltage-Gated Sodium Channels: Structure, Function, and Pathophysiology

W A Catterall, University of Washington, Seattle, WA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Action potential The electrical signal conducted by nerve and muscle cells.

Gating charge A charged amino acid residue in a voltage-gated ion channel whose movement causes gating current and initiates a conformational change that opens or closes the pore.

Gating current A capacitive electrical current caused by movement of charged amino acid residues (the gating charges) in transmembrane segment S4 of voltage-gated ion channels across the membrane.

Ion channels Membrane proteins that form a pore through which ions can cross the membrane.

Ion channelopathy A disease caused by mutation of an ion channel.

Membrane potential The voltage across the plasma membrane of the cell caused by the combination of ion gradients generated by ion pumps and selective ion permeability generated by ion channels.

Voltage sensor The structure within a voltage-gated ion channel that senses and responds to the membrane potential.

Voltage-gated sodium channels initiate action potentials in neurons and other excitable cells, and they are responsible for propagation of action potentials along nerve and muscle fibers. They are complexes of a large pore-forming α -subunit and smaller β -subunits. Multiple genes encode sodium channel subunits, and the distinct sodium channel subtypes have subtle differences in functional properties, differential expression in excitable cells, and differential distribution in subcellular compartments. These differences in function and localization contribute to the specialized functional roles of sodium channels in neuronal physiology and pharmacology. Mutations that alter sodium channel expression and/or function cause several inherited diseases.

Sodium Channel Subunit Structure

Na^+ channel proteins in mammalian brain are complexes of a 260-kD α -subunit in association with one or two auxiliary β -subunits ($\beta 1$ – $\beta 4$) of 33–36 kD in size. The primary sequence predicts that the sodium channel α -subunit folds into four internally repeated domains (I–IV), each of which contains six α -helical transmembrane segments (S1–S6) (Figure 1). In each domain, the S1 through S4 segments serve as the voltage-sensing module, and the S5 and S6 segments and the reentrant P loop between them that folds into the transmembrane region of the channel between them serve as the pore-forming module. A large extracellular loop connects the S5 or S6 transmembrane segments to the P loop in each domain, whereas the other extracellular loops are small. Large intracellular loops link the four homologous domains, and the large N-terminal and C-terminal domains also contribute substantially to the mass of the internal face of sodium channels. This view of sodium channel architecture originally derived from hydrophobicity analysis has been largely confirmed by biochemical, electrophysiological, and structural experiments.

Sodium Channel Genes

Sodium channels are the founding members of the ion channel superfamily that includes voltage-gated Ca^{2+} channels, transient receptor potential (TRP) channels, voltage-gated, inward rectifying, and two-pore-domain K^+ channels, and cyclic nucleotide-regulated (CNG) and hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels. In evolution, the four-domain sodium channel was last among the voltage-gated ion channels to appear, and it is only found in multicellular organisms. It is thought that sodium channels evolved by two rounds of gene duplication from ancestral single-domain bacterial sodium channels like NaChBac found in *Bacillus halodurans*. Voltage-gated sodium channel genes are present in a wide variety of metazoan species including fly, leech, squid, and jellyfish. The biophysical properties, pharmacology, gene organization, and even intron-splice sites of these invertebrate sodium channels are largely similar to the mammalian sodium channels, adding further support for the idea that the primordial sodium channel was established before the evolution of vertebrates.

The human, mouse, and rat sodium channel genes and proteins are the best characterized to date. Ten related sodium channel genes are found in vertebrates (Figure 2). Genes encoding sodium channels $\text{Na}_v 1.1$, $\text{Na}_v 1.2$, $\text{Na}_v 1.3$, and $\text{Na}_v 1.7$ are localized on chromosome 2 in human and mouse, and these channels share similarities in sequence, biophysical characteristics, block by nanomolar concentrations of tetrodotoxin (TTX), and broad expression in neurons. A second cluster of genes encoding $\text{Na}_v 1.5$, $\text{Na}_v 1.8$, and $\text{Na}_v 1.9$ channels is localized to human chromosome 3p21–24 and to chromosome 3 in mouse. Although they are more than 75% identical in sequence to the group of channels on chromosome 2, these sodium channels all contain amino acid substitutions that confer varying degrees of resistance to the pore blocker TTX. In $\text{Na}_v 1.5$, the principal cardiac isoform, a single amino acid change from phenylalanine to cysteine in the pore region of domain I is responsible for 200-fold reduction in TTX

Figure 1 Transmembrane organization of sodium channel subunits. The primary structures of the subunits of the voltage-gated ion channels are illustrated as transmembrane folding diagrams. Cylinders represent probable alpha helical segments. Bold lines represent the polypeptide chains of each subunit with length approximately proportional to the number of amino acid residues in the brain sodium channel subtypes. The extracellular protein domains of the $\beta 1$ and $\beta 2$ subunits are shown as immunoglobulin-like folds. Ψ , sites of probable N-linked glycosylation; P, sites of demonstrated phosphorylation by PKA (circles) and PKC (diamonds); shaded, pore-lining S5-P-S6 segments; white circles, the outer (EEDD) and inner (DEKA) rings of amino residues that form the ion selectivity filter and the tetrodotoxin binding site; ++, S4 voltage sensors; h in blue circle, inactivation particle in the inactivation gate loop; blue circles, sites implicated in forming the inactivation gate receptor. Sites of binding of α - and β -scorpion toxins and a site of interaction between α and $\beta 1$ subunits are also shown. The colors in the transmembrane segments are correlated with the 3D model in Figure 3. Blue and green, the voltage-sensing module composed of S1–S4; yellow, orange, and red, the pore-forming module composed of S5, P, and S6.

Figure 2 Amino acid sequence similarity and phylogenetic relationships of voltage-gated sodium channel α subunits. Phylogenetic relationships of rat sodium channel sequences $\text{Na}_v1.1$ – $\text{Na}_v1.9$ and Na_x . To perform the analysis, the amino acid sequences for all of the isoforms were aligned and identical residues identified using Clustal W. Divergent portions of the terminal regions and the cytoplasmic loops between domains I–II and II–III were excluded from the analysis. The tree was rooted by including the invertebrate sodium channel sequences.

sensitivity compared to those channels on chromosome 2. At the identical position in $\text{Na}_v1.8$ and $\text{Na}_v1.9$, the amino acid residue is serine, and this change results in even greater resistance to TTX. These two channels are preferentially expressed in peripheral sensory neurons. In comparison to the sodium channels on chromosomes 2 and 3, $\text{Na}_v1.4$ which is expressed in skeletal muscle and $\text{Na}_v1.6$ which is highly abundant in central nervous system (CNS) have greater than 85% sequence identity and similar functional properties, including TTX sensitivity in the nanomolar concentration range. $\text{Na}_v1.4$ and $\text{Na}_v1.6$ are located on human chromosome

11 (mouse chromosome 17) and human chromosome 15 (mouse chromosome 12), respectively.

A tenth sodium channel, Na_x , whose gene is located near the sodium channels of chromosome 2, is evolutionarily more distant. Key differences in functionally important regions of voltage sensor and inactivation gate and lack of functional expression of voltage-gated sodium currents in heterologous cells suggest that Na_x may not function as a voltage-dependent sodium channel. Consistent with this conclusion, targeted deletion of the Na_x gene in mice causes functional deficits in sensing plasma salt levels but not in electrical excitability.

The $\text{Na}_v\beta$ subunits are encoded by four distinct genes in mammals. The $\beta 1$ and $\beta 3$ subunits associate noncovalently with the α subunits, whereas $\beta 2$ and $\beta 4$ are covalently linked by a disulfide bond. All four β subunits have a single transmembrane segment, a large N-terminal extracellular domain, and a small intracellular C-terminal domain (Figure 1). The $\text{Na}_v\beta$ subunits are dual-function proteins. Co-expression of $\text{Na}_v\beta$ subunits alters the kinetics and voltage dependence of activation and inactivation of sodium channel complexes. Moreover, their extracellular domain forms an immunoglobulin-like fold, similar to many cell-adhesion molecules, and the β subunits are involved in interactions of sodium channels with proteins in the extracellular matrix, with other cell-adhesion molecules, and with intracellular regulatory proteins like protein kinases and phosphoprotein phosphatases. The importance of the functions of the $\text{Na}_v\beta$ subunits is underscored by the strong effects of deletion of the genes encoding $\text{Na}_v\beta 1$ and $\text{Na}_v\beta 2$, which include impairments of myelination and axonal conduction, epileptic seizures, and premature death.

Expression and Localization of Sodium Channel Subtypes

The sodium channel subtypes are differentially expressed in tissues and differentially localized within individual cells. $\text{Na}_v1.3$ is highly expressed in fetal nervous tissues, whereas $\text{Na}_v1.1$, $\text{Na}_v1.2$, and $\text{Na}_v1.6$ are abundant in juvenile and adult CNS. Generally, $\text{Na}_v1.1$ and $\text{Na}_v1.3$ are primarily localized in neuronal cell bodies where they may control the neuronal excitability through integration of synaptic impulses to set the threshold for action potential generation and propagation to the dendritic and axonal compartments. $\text{Na}_v1.2$ is primarily localized in unmyelinated axons. During development, $\text{Na}_v1.6$ replaces $\text{Na}_v1.2$ in maturing nodes of Ranvier in myelinated axons. $\text{Na}_v1.1$, $\text{Na}_v1.2$, and $\text{Na}_v1.6$ are also expressed in the peripheral nervous system. However, the three isoforms that have been cloned from sympathetic and dorsal root ganglion neurons, $\text{Na}_v1.7$, $\text{Na}_v1.8$, and $\text{Na}_v1.9$ are more abundant and are the principal sodium channels in the peripheral nervous system. The $\text{Na}_v1.7$ channel is localized in axons, where it functions in initiating and conducting the action potential. More restricted expression patterns are observed for $\text{Na}_v1.8$ and $\text{Na}_v1.9$; these channels are highly expressed in small sensory neurons of dorsal root ganglia and trigeminal ganglia where they have a key role in nociception. $\text{Na}_v1.4$ and $\text{Na}_v1.5$ are the primary muscle sodium channels that control the excitability of the skeletal and cardiac myocytes, respectively. $\text{Na}_v1.5$ is transiently expressed in developing skeletal muscle but is replaced by $\text{Na}_v1.4$ in the adult.

Molecular Basis of Sodium Channel Function

Classical work by Hodgkin and Huxley defined the three key features of sodium channels: (1) voltage-dependent activation, (2) rapid inactivation, and (3) selective ion conductance. Building on this foundation, recent structure–function studies employing molecular, biochemical, structural, and electrophysiological techniques have provided clear understanding of the molecular basis of sodium channel function. The narrow outer pore is formed by the re-entrant P loops between transmembrane segments S5 and S6 of each domain (**Figure 1**). Mutation of a set of four residues in analogous positions in each domain (aspartate in domain I, glutamate in domain II, lysine in domain III, and alanine in domain IV, DEKA) to glutamates confers calcium selectivity, indicating that the side chains of these amino acid residues are likely to interact with sodium ions as they are conducted through the ion selectivity filter of the pore.

Similar to other voltage-gated ion channels, the voltage dependence of activation of sodium channels derives from outward movement of gating charges as a consequence of depolarization of the membrane and reduction of membrane electric field. The S4 segments of each homologous domain serve as the primary voltage sensors for activation. They contain repeated motifs of a positively charged amino acid residue followed by two hydrophobic residues creating a transmembrane spiral of positive charges. Upon depolarization, outward movement and rotation of S4 is thought to initiate a conformational change that opens the sodium channel pore. This sliding helix model is

supported by strong evidence. For example, neutralization of the positively charged residues in S4 reduce the voltage dependence of gating. The outward and rotational gating movement of S4 segment has been detected directly by reaction of substituted cysteine residues in S4 segments with extracellular sulfhydryl reagents following channel activation and by analysis of the movement of fluorescent probes incorporated into these substituted cysteine residues. A structural model of the voltage-sensing and pore-forming modules of sodium channels in the resting and activated states is illustrated in **Figure 3**, and movies of the gating movements of the voltage sensor and pore modules during activation and opening of the sodium channel are presented online (**Movies 1 and 2**; see section **Relevant Website**).

Fast inactivation of the sodium channel is a critical process that occurs within milliseconds of channel opening. The generally accepted model of this process involves a conserved inactivation gate formed by the intracellular loop connecting domains III and IV, which serves as a hinged lid that binds to the intracellular end of the pore and blocks it (**Figure 1** and see below). Intracellular perfusion of proteases or intracellular application of antibodies directed to this loop prevents fast inactivation. The latch of this fast inactivation gate is formed by three key hydrophobic residues, IFM, and an adjacent threonine (T). Mutations of these amino acid residues destabilize the inactivated state, and peptides harboring the IFM motif can restore inactivation to sodium channels having mutated inactivation gates. The closed inactivation gate is thought to make multiple interactions with hydrophobic amino acid residues near the intracellular mouth of the pore that may constitute the inactivation gate receptor. Scanning mutagenesis experiments implicate hydrophobic residues in intracellular S4–S5 loops of domains III and IV, as well as the intracellular end of the S6 transmembrane segment in domain IV in forming the inactivation gate receptor.

Three-Dimensional Structure of Sodium Channels

The three-dimensional (3D) structure of the sodium channel is not yet completely known, but some limited structural information has emerged. Structural determination at 19 Å resolution by cryo-electron microscopy and image reconstruction techniques shows sodium channels as having a bell shape from a side view, a four-fold symmetry of transmembrane masses as viewed from above the membrane, and large intracellular and extracellular masses through which several inlets and outlets allow aqueous access (**Figure 3(a)**). Unexpectedly, this image of sodium channels reveals a central pore that does not directly connect the intracellular and extracellular spaces, instead splitting into four branches near the membrane surface. Moreover, it suggests the presence of four peripherally located narrow transmembrane pores, which may function as gating pores for voltage-sensor movement as described below.

The only high-resolution structure of sodium channels is the solution structure of the inactivation gate in the intracellular loop connecting domains III and IV, as determined by nuclear magnetic resonance (NMR) analysis of this intracellular loop expressed in bacteria (**Figure 3(b)**). This structural analysis reveals a rigid alpha helical structure, preceded by

Figure 3 3D structure of sodium channels and a related potassium channel. (a) The 3D structure of the Na_v channel α subunit at 20 Å resolution, compiled from electron micrograph reconstructions. (b) (Top) The hinged-lid mechanism. The intracellular loop connecting domains III and IV of the sodium channel is depicted as forming a hinged lid with the critical phenylalanine (Phe1489) within the IFM motif shown occluding the mouth of the pore during the inactivation process. The circles represent the transmembrane helices. (Bottom) 3D structure of the central segment of the inactivation gate as determined by multi-dimensional NMR. Isoleucine 1488, phenylalanine 1489, and methionine 1490 (IFM) are illustrated in yellow. Threonine 1491, which is important for inactivation, and serine 1506, which is a site of phosphorylation and modulation by protein kinase C, are also indicated. (c) K_v1.2 models of the closed and open states shown in cylinder representation. Only a single voltage-sensing module is shown attached to the tetramer of the pore-forming module for clarity. Transmembrane segments S1 through S6, and P-loop colored by rainbow scheme from blue to red. The S4–S5 linker colored by purple color. Approximate positions of the alpha carbon atoms of the first and fourth gating charge carrying arginines in the S4 (labeled as R1 and R4 and colored in blue) and E226 in the S2 (labeled as E1 and colored in red) shown in sphere representation. All intracellular and extracellular loops, except for the S4–S5 linker, are represented by curved lines for simplicity. Vertical translation of the R4 between the closed and open states along the membrane normal vector and relative to the plane of the membrane indicated by arrows. The S3 represented by ribbon to show clearly the positions of the gating-charge-carrying arginines in the S4 segment. (a) Adapted from Sato C, Ueno Y, Asai K, et al. (2001) The voltage-sensitive sodium channel is a bell-shaped molecule with several cavities. *Nature* 409: 1047–1051. (b) Adapted from Catterall WA (2000) From ionic currents to molecular mechanisms: The structure and function of voltage-gated sodium channels. *Neuron* 26: 13–25.

two turns that position the key hydrophobic sequence motif IFMT such that it can interact with and block the inner mouth of the pore.

The global fold of the sodium channel pore region is predicted to be similar to that of voltage-gated potassium channels (Figure 3(c)). The structure of the open state of this channel has been determined by X-ray crystallography, and the structure of the closed state has been determined by structural

modeling using the Rosetta method. This structural view shows the S5 and S6 region of sodium channel arrayed in four-fold symmetry around the aqueous ion-conduction pathway (Figure 3(c), red, tan, and yellow). The selectivity filter of the pore at its narrow extracellular end is formed by the P loops (tan), whereas the wider vestibule in the center of the pore is a narrow pore formed mostly by the S6 segments (red). A single voltage-sensor module is illustrated for simplicity (Figure 3(c),

blue and green). In the resting (closed) state of the channel, the S4 segment is in an inward position. Activation of the voltage sensor by depolarization causes outward and rotational movement of the S4 segment and complementary movement of the S1, S2, and S3 segments around it (see [Movies 1](#) and [2](#) at the PNAS website; see section [Relevant Website](#)). These coupled molecular movements translocate the gating charges in the S4 segment from exposure to the intracellular milieu to exposure to the extracellular milieu, as required for voltage-dependent gating.

Comparison of the primary structures of the auxiliary β subunits to those of other proteins reveals a close structural relationship to the family of proteins that contain immunoglobulin-like folds, which include many cell-adhesion molecules. The extracellular domains of these type-I single-membrane-spanning proteins are predicted to fold in a similar manner as myelin protein P0, whose immunoglobulin-like fold is known to be formed by a sandwich of two beta sheets held together by hydrophobic interactions ([Figure 1](#)). Myelin P0 protein is a cell-adhesion molecule involved in tight wrapping of myelin sheets, and many related cell-adhesion molecules with extracellular Ig-folds and a single membrane-spanning segment are involved in cell–cell interactions among neurons and glia. As expected from their structure, $\text{Na}_v\beta$ subunits interact with extracellular matrix molecules, other cell-adhesion molecules, and intracellular cytoskeletal proteins and signaling proteins. These interactions are thought to localize and stabilize sodium channels in specific subcellular compartments such as axon hillocks and nodes of Ranvier where they are present in high density and to bring crucial signaling molecules to the sodium channel to regulate it.

Sodium Channel Pharmacology

Sodium channels are the molecular targets for drugs used in prevention of acute pain in dentistry and surgery and in treatment of cardiac arrhythmias, epilepsy, and the manic phase of bipolar disorder. Sodium channel-blocking drugs are also in development for treatment of chronic pain. Local anesthetics bind to a specific receptor within the pore of sodium channels, formed by the S6 segments in domains I, III, and IV ([Figure 4](#)). Their binding blocks ion movement through the pore and stabilizes the inactivated state of sodium channels. Antiarrhythmic drugs and anti-epileptic drugs share similar, overlapping receptor sites. Complete block of sodium channels would be lethal. However, these drugs selectively block sodium channels in depolarized and/or rapidly firing cells, such as axons carrying high-intensity pain information and rapidly firing nerve and cardiac muscle cells that drive epileptic seizures or cardiac arrhythmias. This selective block arises because the drugs can reach their binding site in the pore of the sodium channel more rapidly when the pore is repetitively opened and they bind with high affinity to inactivated sodium channels that are generated in rapidly firing or depolarized cells. This use-dependent action of the sodium channel-blocking drugs is essential for their therapeutic efficacy.

In addition to these important pharmaceutical agents, sodium channels are the molecular targets for a large number of neurotoxins that paralyze prey by preventing neuromuscular function ([Table 1](#)). These toxins act at five or more distinct

Figure 4 Model of etidocaine binding to the local anesthetic receptor site formed by transmembrane segments IS6, IIIS6, and IVS6 of the $\text{Na}_v1.2$ channel. 3D model of proposed orientation of amino acid residues within the Na^+ channel pore with respect to the local anesthetic etidocaine. Only transmembrane segments IS6 (red), IIIS6 (green), and IVS6 (blue) are shown. Residues important for etidocaine binding are shown in space-filling representation.

Table 1 Receptor sites on sodium channels

Receptor site	Toxin or drug	Location (domain/segment)
Neurotoxin receptor site 1	Tetrodotoxin Saxitoxin	I/P, II/P, III/P, IV/P I/P, II/P, III/P, IV/P
Neurotoxin receptor site 2	μ -Conotoxin Veratridine Batrachotoxin Grayanotoxin	I/S6, IV/S6
Neurotoxin receptor site 3	α -Scorpion toxins Sea anemone toxins	I/S5–IS6, IV/S1–S2, IV/S3–S4 IV/S3–S4
Neurotoxin receptor site 4	β -Scorpion toxins	II/S1–S2, II/S3–S4
Neurotoxin receptor site 5	Brevetoxins	I/S6, IV/S5
Neurotoxin receptor site 6	Ciguatoxins δ -Conotoxins	IV/S3–S4
Local anesthetic receptor site	Local anesthetic drugs Antiarrhythmic drugs Antiepileptic drugs	I/S6, III/S6, IV/S6

receptor sites and either block the pore of the channel or alter the kinetics or voltage dependence of gating. The pore blockers TTX and saxitoxin bind to neurotoxin receptor site 1, which is formed by the P loops in the four domains. Alkaloids and other organic toxins from plants, frogs, and other species bind at neurotoxin receptor site 2 and cause persistent activation of sodium channels, which depolarizes nerves and muscles and causes repetitive firing and paralysis. Polypeptide toxins from scorpions and spiders bind at neurotoxin receptors sites 3 and 4 and either slow inactivation or enhance activation of sodium channels, which also causes repetitive firing and paralysis. Brevetoxins and ciguatoxins, which are large polyether

Table 2 Major inherited diseases of sodium channels

Disease	Gene	Channel
Generalized epilepsy with febrile seizures plus	SCN1A	Na _v 1.1
Severe myoclonic epilepsy in infancy	SCN1A	Na _v 1.1
Familial hemiplegic migraine type III	SCN1A	Na _v 1.1
Benign familial neonatal-infantile seizures	SCN2A	Na _v 1.2
Hypokalemic periodic paralysis type II	SCN4A	Na _v 1.4
K ⁺ -sensitive normokalemic periodic paralysis	SCN4A	Na _v 1.4
Hyperkalemic periodic paralysis	SCN4A	Na _v 1.4
Paramyotonia congenita	SCN4A	Na _v 1.4
Long QT syndrome type III	SCN5A	Na _v 1.5
Brugada syndrome	SCN5A	Na _v 1.5
Erythromelalgia	SCN9A	Na _v 1.7
Paroxysmal extreme pain disorder	SCN9A	Na _v 1.7
Congenital indifference to pain	SCN9A	Na _v 1.7

compounds made by marine dinoflagellates, bind to neurotoxin receptor site 5 and cause persistent activation of sodium channels. The diversity of organisms that have developed toxins that target sodium channels is remarkable, highlighting the physiological importance of these channels in electrical signaling and neuromuscular function.

Sodium Channelopathies

Mutations that alter sodium channel function lead to human diseases of hyperexcitability (Table 2). Multiple mutations of Na_v1.4 that yield hyperactive skeletal muscle sodium channels have been shown to cause hyperkalemic periodic paralysis and paramyotonia congenita. By contrast, mutations in S4 gating charges that cause reduced function of these channels and induce a sodium leak through their mutant voltage sensor domains (termed 'gating pore current') cause hypokalemic periodic paralysis. Mutations of Na_v1.5 that impair inactivation or decrease expression and/or activation lead respectively to inherited long QT syndrome type 3 and Brugada syndrome, in which the risk of fatal cardiac arrhythmias is greatly increased.

Familial febrile seizures, generalized epilepsy with febrile seizure plus (GEFS⁺) type II, and severe myoclonic epilepsy of Infancy (SMEI) all result from mutations of Na_v1.1 channels. These mutations selectively impair electrical excitability and action potential firing in inhibitory neurons in the brain and thereby cause hyperexcitability and epilepsy by disinhibition of excitatory neuron activity. A spectrum of severity of these loss-of-function mutations causes the spectrum of severity of these disease syndromes: SMEI >> GEFS⁺ >> familial febrile seizures. By contrast, gain-of-function mutations in Na_v1.1 channels cause familial hemiplegic migraine type-II. Benign familial neonatal-infantile seizures are caused by mutations in Na_v1.2 channels, which reduce cell surface expression and decrease functional activity of these channels.

The sodium channels expressed in the peripheral nervous system also are the targets for mutations that cause inherited

disease syndromes. Mutations that cause different functional effects on Na_v1.7 channels are responsible for three distinct disease syndromes. Mutations that enhance activation of Na_v1.7 channels cause inherited erythromelalgia, characterized episodes of burning pain, erythema, and mild swelling in the hands and feet triggered by mild warmth or exercise, whereas mutations that impair fast inactivation cause paroxysmal extreme pain disorder, characterized by intense rectal pain. By contrast, loss-of-function mutations in Na_v1.7 channels cause congenital insensitivity to pain, which is characterized by complete loss of the sensation of pain without loss of response to other sensory modalities.

The physiological requirement for intact sodium channel function is further underscored by mouse knockout models, in which specific ablation of Na_v1.1, Na_v1.2, Na_v1.5, and Na_v1.6 lead to premature lethality. By contrast, mutant mice lacking Na_v1.7 or Na_v1.8 are viable and have defects in nociceptive response. These and other mouse models that target specific sodium channel genes should prove to be effective in delineating the significance of sodium channel function and its regulation in physiological contexts.

von Hippel–Lindau (VHL) Protein

R C Conaway and J W Conaway, Stowers Institute for Medical Research, Kansas City, MO, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Dioxygenase Enzyme that catalyzes the insertion of both oxygens of molecular oxygen, O₂, into substrate molecules.

Erythropoietin An acidic glycoprotein hormone that regulates red-cell production by promoting erythroid differentiation and the initiation of hemoglobin synthesis.

Hemangioblastoma A highly vascularized tumor composed of capillaries and stromal cells.

Hemangioma A benign lesion originating from blood vessels.

Pheochromocytoma A tumor of the adrenal gland.

Retinal angioma A benign lesion found in the retina that originates from blood vessels.

Vascular endothelial growth factor A growth factor for vascular endothelial cells that promotes angiogenesis.

The von Hippel–Lindau (VHL) protein is a tumor suppressor. Mutations in the VHL protein can give rise to tumors of multiple organ systems, including the central nervous system, the endocrine system, and the kidney. The VHL protein functions as a subunit of a multiprotein ubiquitin ligase that negatively regulates expression of a large collection of hypoxia-inducible genes controlled by hypoxia-inducible transcription factors (HIFs). The VHL ubiquitin ligase prevents inappropriate expression of these hypoxia-inducible genes when cells are grown in a plentiful supply of oxygen by targeting HIFs for rapid ubiquitylation and degradation by the proteasome.

Clinical Consequences of VHL Mutations

Mutations in the *VHL* gene are found in a variety of human diseases, including VHL disease, sporadic clear cell renal carcinoma, sporadic hemangioblastoma, and congenital polycythemia. VHL disease is an autosomal dominant familial cancer syndrome. In VHL kindreds, inactivation of both copies of the *VHL* gene can give rise to a variety of highly vascularized tumors, including clear cell renal carcinoma, cerebellar hemangioblastoma and hemangioma, retinal angioma, and pheochromocytoma. *VHL* mutations are also responsible for the majority of cases of sporadic clear cell renal carcinoma and for sporadic hemangioblastoma. In addition, *VHL* mutations can also give rise to autosomal recessive familial erythrocytosis 2, a disorder characterized by elevated levels of expression of the hypoxia-inducible *erythropoietin* gene.

Function of the VHL Protein

The VHL protein is present in eukaryotes from worms to mammals, where it performs an evolutionarily conserved function as a subunit of a multiprotein ubiquitin ligase that negatively regulates expression of a large number of hypoxia-inducible genes controlled by HIFs. The expression of these hypoxia-inducible genes is repressed in normal cells grown in a plentiful supply of oxygen (normoxic conditions), but is strongly induced in cells starved for oxygen (hypoxic conditions). The VHL ubiquitin ligase prevents the inappropriate expression of these hypoxia-inducible genes when cells are grown in

normoxic conditions by targeting HIFs for rapid ubiquitylation and degradation by the proteasome. When cells are starved for oxygen, ubiquitylation of HIFs by the VHL ubiquitin ligase is blocked. Under these hypoxic conditions, cellular HIF levels rise, and HIFs enter the nucleus, bind to hypoxia response elements (HREs) in the promoters of hypoxia-inducible genes, and activate their transcription and expression.

The cellular levels of HIFs correlate well with the levels of expression of hypoxia-inducible genes in both normoxic and hypoxic conditions (Figure 1). In normal cells growing under normoxic conditions, HIFs are present in cells at low levels, and expression of hypoxic-inducible genes is barely detectable. Under hypoxic conditions, HIFs are present at relatively high levels, and expression of hypoxia-inducible genes is robust. Under both normoxic and hypoxic conditions in cells lacking a functional VHL protein, HIFs are present in cells at high levels, and maximal expression of hypoxia-inducible genes is observed. Inappropriate overexpression of hypoxia-inducible genes in cells lacking a functional VHL protein may contribute to the pathology of VHL-associated diseases. Among these are the genes encoding vascular endothelial growth factor (VEGF), transforming growth factor- α (TGF α), and erythropoietin (EPO). VEGF is a secreted protein that appears to play a major role in the vascularization of VHL tumors by promoting ingrowth into tumors of blood vessels needed to carry oxygen and nutrients to the tumor cells. TGF α is also a secreted protein that appears to function as an autocrine growth factor for some types of VHL tumor cells and may be responsible for promoting their uncontrolled proliferation. An elevated EPO level in the serum of polycythemic patients is a hallmark of the disease.

Structure of the VHL Ubiquitin Ligase

Purification of the VHL ubiquitin ligase revealed that it is composed of multiple proteins. In addition to the VHL protein, the VHL ubiquitin ligase includes the elongin B and C proteins, cullin protein family member Cul2, and RING finger protein Rbx1 (Figure 2). In the VHL ubiquitin ligase, the VHL protein functions to recruit HIFs for ubiquitylation by interacting directly with them. The elongin B and C proteins bind stably to each other to form an adaptor that links the VHL protein to a Cul2-Rbx1 heterodimeric module. The Cul2-Rbx1 module functions

XPV Polymerase and the Bypass of Ultraviolet DNA Damage

Glossary

DNA polymerase Enzymes which are able to synthesize new DNA molecules using a DNA template.

Nuclear localization signal A sequence of amino acids in a protein that results in its localization in the nucleus.

Nucleotide excision repair The enzymatic pathway by which many types of DNA damage are first recognized, then

cut out of the DNA, and the excised region replaced with new DNA.

Ubiquitination A posttranslational modification of a protein in which a molecule of the 76-amino-acid polypeptide ubiquitin is covalently attached to a target protein.

Zinc finger A sequence of amino acids which forms a finger-like structure and binds a zinc atom.

Xeroderma Pigmentosum Variants

All cells sustain many kinds of DNA damage. This can be generated either endogenously from hydrolysis and oxidation reactions or exogenously from exposure to carcinogens. One of the most prevalent DNA-damaging agents is ultraviolet (UV) radiation from the sun, which generates photoproducts in the DNA of cells in exposed areas of the skin. The most important photoproducts, namely the cyclobutane pyrimidine dimer (CPD) and the pyrimidine 6-4 pyrimidone photoproduct (6-4 PP), are removed from cellular DNA by the process of nucleotide excision repair (NER). The importance of this process can be seen from the features of patients with xeroderma pigmentosum (XP). XP patients show a wide variety of skin abnormalities on sun-exposed areas including freckling, hypo- and hyperpigmentation, and ultimately multiple skin cancers. The incidence of skin cancer in XP individuals has been estimated to be 1000-fold higher than that in unaffected individuals. In the majority of XP patients, this hypersensitivity to the effects of sunlight results from a genetic deficiency in NER. In approximately 20% of XP individuals, however, NER is normal. These so-called XP variants (XPVs) are deficient in their ability to produce intact daughter DNA strands during DNA replication after exposure of the cells to UV irradiation. In other words, they are defective in their ability to replicate DNA damaged by UV light.

Pol η and the Y-Family of DNA Polymerases

Although the cellular deficiency in XPV was identified in 1975, the molecular basis for the defect was not discovered until

1999. The gene defective in XPV cells was found to encode a new DNA polymerase designated DNA polymerase η or pol η . Pol η is a protein of 713 amino acids (aa) with no sequence similarity to previously discovered DNA polymerases, but it does share sequence similarity with several other DNA polymerases that were discovered at about the same time. This new group of polymerases were designated the 'Y-family' and they are involved in translesion synthesis (TLS) past different types of damage. They show sequence conservation over a region of about 400 aa, which contains the catalytic domain and usually forms the N-terminal part of the protein. Y-family polymerases have a C-terminal extension, which is not conserved between family members.

Catalytic Activity

DNA polymerases that carry out the replication of undamaged DNA are very efficient and accurate, but they are blocked by most types of DNA damage, including both major UV photoproducts. By contrast, pol η is a rather poor polymerase on undamaged DNA. It dissociates after incorporating a few nucleotides and it is rather error prone. However, pol η , in contrast to all other eukaryotic polymerases, is able to carry out TLS past a T–T CPD with the same efficiency as past undamaged Ts. Furthermore, in most instances, the correct bases, namely two As, are inserted opposite the T's of the CPD. The reason for these properties became clear when the catalytic domains of several members of the Y-family (including yeast pol η) were crystallized and their three-dimensional (3D) structures solved. Despite the lack of sequence similarity between classical and Y-family polymerases, the 3D structures did have

Figure 1 Translesion synthesis by pol η . Replicative DNA synthesis is blocked by a CPD (indicated by red blocks). This leads to a switch to pol η (step 1), which replicates past the CPD (step 2) and then dissociates, so that normal replication can restart (step 3).

the three subdomains, designated finger, thumb, and palm, found in all other DNA polymerases, with the Y-family having an extra subdomain designated pad or little finger. However, whereas the classical polymerases form a closed tight structure, which only permits normal bases into the active site, pol η has a much more open structure, with two important consequences. First, it has a relatively low stringency, so that incorrect bases can be incorporated rather easily. Second, the open structure is able to accommodate the CPD in the template strand and the structure ensures that, in general, the correct bases are inserted opposite the pyrimidines in the CPD. Thus, pol η is tailor-made for replicating past CPDs. It can insert the appropriate bases opposite the damage and extend from these bases, but then it will soon dissociate from the template, so that the more-accurate replicative polymerases can take over again. A simple mechanistic scheme for TLS is shown schematically in Figure 1.

Apart from the CPD, pol η is able to replicate past some other types of damage *in vitro*, but in most cases, it is much less efficient with other types of damaged templates than with undamaged or CPD-containing DNA. Recent data suggest that it may be involved in bypassing other lesions *in vivo*, such as those generated by cisplatin.

The importance of pol η is seen in the severe clinical characteristics of XPV patients and in the very high UV-induced mutation frequency in XPV cells. The UV-mutability of XPV cells is several fold higher than that of normal cells and the frequency of all types of mutations is increased. This indicates that in the absence of pol η , some other enzyme is able to function, but the replacement is less efficient and makes more mistakes.

Localization and Interactions

The catalytic domain of pol η is contained within the first 430 aa. What then is the function of the C-terminal 280 aa? DNA replication takes place during the S phase of the cell cycle in replication factories inside the cell nucleus. These factories can be visualized either by immunofluorescence with an antibody to a replication protein, or by tagging proteins involved in DNA replication with the green fluorescent protein (GFP). The factories appear as bright nuclear foci when viewed by fluorescent microscopy. Pol η localizes in replication factories during the S phase, so that it is always on hand in case the replication machinery encounters DNA damage (Figure 2). It is the C-terminal 120 aa of pol η (aa 595–713) that is responsible for this localization into replication factories. This

Figure 2 Localization of pol η in replication foci. Pol η , tagged with GFP, localizes into nuclear foci during DNA replication.

Figure 3 Domain structure of pol η . C2H2, zinc-finger UBZ motif; NLS, nuclear localization signal; PB, PCNA-binding PIP box motif; FF, foci formation; Ubi, ubiquitin. Bars represent regions involved in interactions with the indicated proteins. hRev1 and pol δ are other Y-family polymerases, hRad18 is a E3 ubiquitin ligase that mono-ubiquitinates PCNA when replication forks are stalled at sites of DNA damage.

C-terminal domain contains three important elements, all of which are needed for localization into foci and for efficient TLS. These are (1) a PIP box that is involved in binding to the replication accessory protein, proliferating cell nuclear antigen (PCNA); (2) a bipartite nuclear localization sequence that is

required for transporting pol η into the nucleus but is also part of the PCNA-interacting region; and (3) a C₂H₂ zinc finger that forms a UBZ ubiquitin-binding motif (UBZ, ubiquitin-binding zinc finger). The function of aa 430–595 in pol η has not yet been determined, but it is involved in interactions with other proteins. The domain structure and regions of interaction of pol η with other proteins are summarized in [Figure 3](#).

The interaction of pol η with the protein hRad18 is also important for localization into foci. It is thought that hRad18 is involved in transporting pol η into replication factories. The interaction of pol η with its cousin pol ι is not required for localization of pol η but it does facilitate the localization of pol ι , which is also found in replication foci in S-phase cells. The interaction with Rev1 is discussed below.

Interaction with Ubiquitinated PCNA and the Polymerase Switch

PCNA is a homotrimeric ring, which acts as a sliding clamp to increase the processivity of all DNA polymerases. When DNA replication is blocked by damage, PCNA becomes ubiquitinated. This ubiquitination increases the affinity of PCNA for Y-family polymerases, because they all have ubiquitin-binding domains in their C-terminal regions. In the case of pol η , this is the UBZ motif. Thus, all three elements in the C-terminus of pol η stimulate its binding to ubiquitinated PCNA. This facilitates its ability to displace the replicative polymerase from the template–primer and, if the damage is a CPD, to carry out TLS past the damaged bases.

Mutations in XPV Patients

Mutations have been identified in the pol η gene in some 60 patients. Most of the mutations result in truncations within the catalytic subunit and would not be expected to result in any functional pol η . This demonstrates that pol η is not an essential protein, because its absence is compatible with life. Several missense mutations within the catalytic domain have also been identified and they are predicted either to inhibit binding to DNA or to interfere with the 3D structure of the protein. A small number of mutations do not affect the catalytic domain, but truncate the protein close to the C-terminus. These mutant proteins would be expected to be fully active, but to lack the localization/interaction domain in the C-terminus, which is required for transporting the polymerase into the nucleus and for its interaction with ubiquitinated PCNA at the stalled fork. There is no clear relationship between the site or type of

mutation and the severity of the clinical features, even though the severity of features differs widely between patients.

Replication Past Other Types of UV Damage

Although the CPD is the major UV photoproduct, the 6-4 PP is also formed in substantial quantities (about one-third the frequency of the CPD). No single polymerase has been found that is able to carry out TLS past a 6-4 PP, which produces a much greater distortion in the DNA than a CPD. However, two polymerases acting in concert are able to accomplish this *in vitro*. Insertion of the nucleotides opposite the 6-4 PP can be carried out either by pol η or by its paralog, pol ι , but neither of these can extend further from the incorporated nucleotides. However, once nucleotides have been inserted opposite the damaged bases, they can be extended by DNA polymerase ζ . So far, direct evidence for this dual polymerase mechanism has only been obtained *in vitro*. It is likely that this mechanism is also used *in vivo*, and, indeed, DNA polymerase ζ is required for TLS past 6-4 PPs inside cells, probably for the extension step. As yet, it is not known which polymerase carries out the insertion step. The interaction of pol η with Rev1 (see [Figure 3](#)) has been proposed to be important for the two-stage insertion–extension mode of TLS. Rev1 interacts via a sequence in its extreme C-terminus with the other three Y-family polymerases as well as with the Rev7 subunit of pol ζ . It is suggested that Rev1 can thereby facilitate the handover from the inserting polymerase (Y-family) to the extender (pol ζ).

Glossary

Classical finger A zinc finger of the TFIIIA type, where a zinc ion is coordinated by two cysteines and two histidines (Cys₂-His₂ or C2H2).

Protein motif A small structural element of a protein with a characteristic fold or shape.

TFIIIA A transcription factor protein from *Xenopus laevis*, in which zinc fingers were originally discovered.

Transcription factor A protein involved in gene regulation that helps to activate or repress the expression of a particular gene.

Zinc finger A small structural protein motif consisting of peptide chain folded around a central chelated (coordinated) zinc ion.

Zinc fingers are small, compact protein subunits, with structured peptide chains folding around chelated zinc ions. Functionally, these subunits carry out a wide variety of tasks within cells by providing stable structural scaffolds and driving critical binding interactions, especially among proteins, DNA, and RNA. Zinc fingers are particularly important in gene regulation, where many proteins employ them to bind DNA in a sequence-specific manner, to activate or inhibit particular genes. Although many families of zinc fingers exist, each with a characteristic fold or structure, perhaps the best studied, is the classical (Cys₂-His₂ or C2H2) type. Classical zinc fingers are extremely versatile, as can be seen by their abundance in nature: over 700 proteins contain such domains in the human genome alone, making them the second most common human protein motif. Zinc fingers may be seen as convenient molecular building blocks, often used in clusters, whose modular nature allows them to be conveniently duplicated, altered, and shuffled by evolution. In a biotechnology context, zinc fingers may be re-engineered to have novel binding properties with numerous applications in both research and medicine.

Zinc Finger Structures and Families

Classical Zinc Fingers

History

The zinc finger motif was discovered in 1985 by Miller, McLachlan, and Klug in a protein responsible for controlling gene expression – the *Xenopus* transcription factor IIIA (TFIIIA). Originally, nine novel consecutive repeats were found, each ~30 amino acids in length. Since every repeat had a conserved pair of cysteines and histidines at defined positions, Klug proposed that

these residues could chelate a zinc ion, stabilizing an independent structural domain, the ‘zinc finger’. Notably, the term finger was derived from the finger-like appearance of the sequences when drawn schematically around a zinc ion, as in [Figure 1\(a\)](#). The repeats found in TFIIIA are now used as a definition of the classical zinc finger, where individual fingers conform to the archetypal consensus sequence shown in [Figure 2](#).

Secondary structure and hydrophobic core

Structural studies revealed that the classical Cys₂-His₂ finger is a simple and compact unit based on an antiparallel β -hairpin packed against an α -helix ([Figure 1\(b\)](#)). In addition to chelating zinc, classical fingers are stabilized at the core by a hydrophobic cluster of residues, converging from three fixed positions (see [Figures 1](#) and [2](#)). Moreover, this hydrophobic triad is highly conserved, often consisting of tyrosine, phenylalanine, and leucine. By contrast, zinc fingers may withstand extensive amino acid substitutions at other positions, without significantly altering the overall structure.

The role of zinc

Small protein domains are inherently unstable and, even though the $\beta\beta\alpha$ fold found in zinc fingers can form around hydrophobic cores alone, the stability of the fold is dramatically improved by zinc chelation. Such stability cannot be obtained using the disulfide bridge – a common extracellular alternative – because of the highly reducing environment inside cells. Consequently, intracellular proteins have solved the problem of stabilizing small domains by utilizing metal-binding sites. Zinc is ideally suited for this purpose as it has a single oxidation state, a fixed and distinguishable ionic radius, and can accommodate both nitrogen and sulfur ligands.

Figure 1 Examples of zinc finger families and folds. (a) A classical Cys₂-His₂ zinc finger is drawn schematically as a string of amino acids (1-letter abbreviations), with cysteine (C) and histidine (H) pairs chelating the central zinc ion. Three circled residues (F, F, L) come together in the structure to form a hydrophobic core. The finger shown is Finger 2 from the mouse transcription factor Zif268. (b) Representation of the actual $\beta\alpha$ structure of a classical Cys₂-His₂ zinc finger. Note the position of the hydrophobic core ($h\phi$). (c) A Cys₄ steroid-receptor zinc finger from the estrogen receptor. Note that this protein actually contains two contiguous Cys₄ zinc finger repeats, forming a single structural unit. (d) A Cys₃-His zinc finger from a viral nucleocapsid protein. (e) A yeast GAL4 domain. (f) The ring finger fold.

Figure 2 Zinc finger amino-acid sequences. (a) Consensus sequence of a classical Cys₂-His₂ zinc finger, where X is any amino acid and ϕ represents hydrophobic residues (typically Y, F, and L). Zinc-chelating cysteine and histidine residues are circled. α -Helical positions (numbered relative to position +1) are indicated above the sequence. (b) The sequence of Finger 2 of Zif268, showing conformity with the consensus sequence.

Evolution

Zinc fingers may have evolved originally from peptides, which maintained a simple $\beta\alpha$ structure (similar to that shown in Figure 1(b)) independently of zinc. In any case, the $\beta\alpha$ fold is one of the smallest possible units of protein tertiary structure, and may therefore be one of the oldest. Zinc fingers are abundant in nature and the huge variety found in various organisms, from yeast to human, may in part be due to their modular nature. In this regard, not only are zinc fingers independently folding structural building blocks, but they also are often encoded by single exons. Indeed, exon shuffling and gene duplication may account for why zinc fingers have spread so widely during evolution.

Genomic abundance

The recent initial drafts of the human genome have revealed the extent to which classical zinc fingers are used by cells: there are 706 genes containing one or more classical zinc fingers in humans, totaling several thousand fingers, and making them the second most common human protein family. It is remarkable that only immunoglobulin domains are more abundant in humans, and indeed only slightly more so, being found in 765 genes. By contrast, the *Drosophila melanogaster* fly has 357 classical zinc finger genes, actually making these the most common protein family in this organism. Despite the fact that zinc finger usage varies from organism to organism, these motifs are clearly a widespread feature in all eukaryotic cells.

Nonclassical Zinc Fingers

Although zinc-binding proteins have been known for many years, the usual definition of zinc fingers maintains that they are distinct from other zinc-binding protein subregions by virtue of being autonomously folding, functional mini-domains. Following the discovery of the classical Cys₂-His₂ zinc finger, many other classes of zinc finger have emerged. Although these form a diverse collection, often with radically different folding topologies, these proteins are often referred to in the literature as zinc fingers. Therefore, some well-studied examples are outlined here below.

Cys₄ zinc fingers

One of the best-characterized nonclassical zinc fingers is the Cys₄ type, including the steroid-hormone receptor family. The estrogen receptor (Figure 1(c)) was the first protein of this type to be elucidated structurally and the gene contains two Cys₄ zinc finger repeats, forming a single structural unit that is quite unlike the independent classical zinc fingers of TFIIIA. Functionally, the steroid receptors form dimers, which bind hormones such as estrogen, and then mediate activation of gene expression through sequence-specific DNA-binding interactions in the promoter regions of target genes. Further examples of proteins containing Cys₄ finger motifs include other nuclear hormone receptors, such as the glucocorticoid and retinoic acid receptors. Many Cys₄ proteins function as transcription factors, such as the elongation factor TFIIIS and the adenoviral E1A transactivator.

Cys₃-His zinc fingers

The Cys₃-His zinc finger is another variant defined by its characteristic combination of cysteine and histidine residues. For example, the nucleocapsid protein, found in certain viruses such as HIV, contains Cys₃-His fingers, with various nucleic-acid-binding properties that facilitate hybridization and the viral life cycle (Figure 1(d)). Other examples of Cys₃-His proteins include MetRS and the first finger in the LIM domain.

Multi-zinc proteins

Moving beyond the simpler zinc finger domains, which fold around a single zinc ion, there exist larger more complex folds, each employing two or more zinc ions. Examples include the yeast GAL4 domain (Figure 1(e)) and the ring finger (Figure 1(f)). Note that although these larger domains are

not quite as prevalent as the single-zinc modules, they nonetheless form quite abundant families. For example, the ring finger family ranks as the 15th most abundant domain in the human genome, with 210 members, while another fold, the PHD finger, ranks 34th with 84 members.

Zinc Finger Functions

Interactions with DNA and RNA

Since their discovery, zinc fingers have been associated with binding nucleic acids, namely, DNA and RNA. Indeed, the archetypal zinc finger protein, TFIIIA, is bifunctional, having distinct modes of binding which allow it to bind both to the DNA internal control region of 5S RNA genes and to the transcribed RNA gene product. In this sense, zinc fingers are master gene regulators, with the potential to influence both transcription and translation.

Structure of zinc finger bound to DNA

The majority of our knowledge of zinc finger functions has focused on their ability to bind specific DNA sequences. The first structure of zinc fingers bound to DNA, that of the DNA-binding domain of the mouse transcription factor Zif268, was solved by Carl Pabo and colleagues in 1991. The structure revealed that each of the three classical zinc fingers occupies the major groove, wrapping around the DNA for almost one turn of the double helix (Figure 3(a)). The base-specific contacts occur primarily from consecutive turns of the zinc finger α -helices to the guanine-rich strand of the DNA.

DNA-recognition helix

Essentially, classical zinc fingers use the α -helix as a reading head to recognize specific DNA sequences. Contacts from amino acids consist primarily of electrostatic interactions and hydrogen bonds, although hydrophobic interactions also play a role. Conventionally, the amino acids in the α -helix are numbered relative to a defined first position – position +1 (see Figures 2 and 3). Since positions –1, +3, and +6 are all to be found on the external face of the helix, these can form a binding surface that is especially useful in DNA recognition because the spacing of the residues matches the register of the base pairs. It should be noted, however, that contacts from other positions, especially position +2, are also important in DNA recognition and that not all zinc finger–DNA interactions are as regular as the canonical structure of Zif268.

DNA-recognition code

The most striking feature of the canonical Zif268 structure is the presence of regularly spaced one-to-one contacts between amino acids and DNA bases, from the same fixed helical positions in each finger (Figure 3(b)). By studying mutations at these positions, it has emerged that classical zinc fingers are a special case in terms of protein–DNA interactions. Unlike for most DNA-binding proteins, these positions do seem to fit a residue-base code-like pattern. Positions –1, +2, +3, and +6 in the α -helix are particularly important (Figure 3(b)), and some major residue-base associations are outlined in Figure 3(c).

As a note of caution, it is important to mention that the code is not absolute, and is certainly an oversimplification

Figure 3 Interactions between zinc fingers and DNA. (a) Side view of Zif268 binding DNA. The three zinc fingers (F1–F3) bind the major groove of the DNA (b) Schematic diagram of a simple model of recognition between the three zinc fingers of Zif268 and the triplet sub-sites of an optimized DNA-binding site. Arrows indicate contacts by recognition residues with bases in each DNA strand. Note that most contacts are to the G-rich strand. Since the N-terminal finger contacts the 3'-end of the DNA and the C-terminal finger the 5'-end, binding is said to be antiparallel. (c) Zinc finger DNA-recognition code. The grid summarizes common associations between amino acid residues (A–Y) and the bases they face in a classical zinc finger DNA-binding site. Darker shading of boxes indicates stronger associations. Note that contacts from overlapping C-terminal zinc fingers (especially from position 2) can significantly alter the coding specificity shown here for position +6. (a) From Pavletich NP and Pabo CO (1991) Zinc finger-DNA recognition: Crystal structure of a Zif268-DNA complex at 2.1 Å. *Science* 252: 809–817.

of the interplay between different residues in the protein and between factors in the DNA structure, such as base stacking and unwinding. Nonetheless, thinking about zinc finger DNA interactions in this way can give a valuable approximation into the possible binding modes of a given zinc finger protein.

RNA recognition

Unlike the double-helical scaffold of DNA, RNA has much more complex folds, with every RNA presenting a unique binding surface. Nonetheless, zinc fingers have the versatility to accommodate such structures, with contacts from all over the finger framework. Like DNA recognition, electrostatic interactions and hydrogen bonding play a major role, with amino acids contacting either RNA bases or the phosphodiester backbone. Note that in RNA recognition, there is a greater potential for hydrophobic interactions, with aromatic residues such as Tyr, Phe, and Trp stacking around extruding bases.

Non-Nucleic Acid Interactions

Protein–protein interactions

Zinc fingers are not limited to controlling gene expression, but play an important cellular role in mediating specific protein–protein interactions as well. Whereas nucleic acid recognition usually requires clusters of fingers, cytoplasmic proteins often contain only one or two fingers. This is possibly because a single protein-binding finger has sufficient affinity to bind effectively, given the more variable binding surface presented by other proteins.

Lipid binding

Recently, the known binding repertoire of zinc fingers has been extended to include lipid recognition. This is exemplified by the FYVE zinc finger family, which is found in a wide range of eukaryotic cells. These nonclassical fingers have a complex structure consisting of multiple loops, two twin-stranded β -sheets, and an α -helix stabilized by a pair of zinc ions. Functionally, the domains bind to phosphatidylinositol 3-phosphate (PI3P) in cellular membranes, commonly found on endosomes, and mediate further recruitment of a range of proteins.

Zinc Fingers in Biotechnology

Classical zinc fingers are the ideal scaffold for protein engineering. They are small and versatile, withstanding extensive mutations without destroying their basic structure. Moreover, individual finger modules may be linked in tandem repeats to allow recognition of extended target surfaces such as DNA grooves. Novel DNA-binding zinc fingers have been routinely engineered for over 15 years and are beginning to demonstrate their utility in biotechnical applications. By fusing with suitable effector domains, effective transcription activators and repressors can be synthesized that recognize specific DNA sequences, typically 9–18 bp long. These constructs can upregulate or downregulate specific genes in a cell and have been used in a wide variety of contexts, including antiviral agents and angiogenesis-promoting factors. Zinc finger nucleases are the latest technological application and have been used to cut and repair genes inside cells and organisms.

protein biosynthesis elongation
 basic concepts, 4:128–129
 elongation phase, 4:122–123, 4:123f,
 4:124f, 4:131, 4:421–423
 schematic diagram, 4:129f
ribosomal subunits, 4:130f, 4:131
structural characteristics, 4:134f
tRNA synthetases, 4:441
5-aminolevulinic acid (ALA), 1:501,
 2:539–540, 2:540f, 3:544, 3:545f, 3:547,
 3:548f
aminolevulinic acid (ALA) synthase (ALAS),
 2:539–540, 2:540f, 2:541–542, 2:542t
aminopeptidases, 1:97–99
 Ape1 protein, 1:151, 1:151f, 2:4f, 2:5t, 2:6,
 2:7
 characteristics, 1:97
 methionine aminopeptidases (MetAPs)
 general discussion, 1:97–99
 isoform functions, 1:98–99
 metal use, 1:98
 structural organization, 1:98, 1:98f
 substrate specificity, 1:98
 N-terminal cotranslational processing,
 1:97–99
 physiological functions, 1:97
 vacuole transport pathways, 1:151,
 4:503–506, 4:504f, 4:505f
aminophospholipid flippases, 2:314–315,
 2:315f, 2:316t
amino-terminal transactivation domain
 (TAD-N), 4:67, 4:68f, 4:70
aminotransferases, 3:564
Amish infantile epilepsy, 2:471t
Amish lethal microcephaly, 1:209
ammonia
 insect biochemistry, 2:591–592, 2:592f
 starvation-based renal ammonia
 formation, 1:109, 4:298, 4:305–306
 urea cycle disorders, 4:494–501
 arginase deficiency (hyperargininemia),
 4:500
 argininosuccinate lyase (AL) deficiency
 (argininosuccinic aciduria),
 4:499
 carbamyl phosphate synthetase (CPS)/
 N-acetylglutamate (NAG)
 synthetase deficiencies, 4:497–498
 citrin deficiency
 adult-onset citrullinemia, 4:499
 characteristics, 4:499
 neonatal intrahepatic cholestasis,
 4:499
 citrullinemia
 argininosuccinate synthetase (AS)
 deficiency, 4:498–499
 citrin deficiency, 4:499
 hyperammonemia
 clinical manifestations, 4:494
 diagnosis, 4:494–495, 4:496f
 inborn errors, 4:494, 4:495t
 long-term therapy considerations,
 4:497
 treatments, 4:495–497, 4:497t
 hyperammonemia–hyperornithinemia–
 homocitrullinemia (HHH)
 syndrome, 4:495f, 4:495t,
 4:500–501
 N-acetylglutamate (NAG) synthetase,
 4:494–495, 4:495f, 4:495t,
 4:497–498
 ornithine transcarbamylase (OTC)
 deficiency, 4:498
 retinal and choroidal gyrate atrophy,
 4:500
 transient hyperammonemia, 4:500
 urinary nitrogen excretion, 4:306f
ammoniaogenesis, 1:95, 4:298, 4:305–306
AMPA (α -amino-3-hydroxy-5-methyl-4-
isoxazolepropionic acid)
AMPA receptors
 excitotoxicity, 1:425f
 functional role, 2:714–716, 2:715t
 kinesin superfamily proteins (KIFs),
 2:681–684, 2:685f
 molecular structure, 2:716t, 2:717–718,
 2:717f, 2:718f
 serine–threonine phosphatases, 4:222f
 functional role, 2:714–716, 2:715t
 molecular structure, 2:716t, 2:717–718,
 2:717f, 2:718f
 schematic diagram, 1:425f
AMP-activated protein kinase (AMPK)
 body weight regulation, 4:58f
 cellular fatty acid metabolism regulation,
 4:56
 diabetes treatments
 metformin, 1:657
 weight loss and exercise, 1:657
 fatty acid metabolism regulation, 2:286
 fatty acid synthesis pathway, 2:275–279,

 light harvesting complexes, 2:726
 PscB protein, 2:339–340, 2:339f
 reaction centers, 2:335, 2:337–338
 light harvesting complexes, 2:726
 reaction centers, 2:507–508, 2:508f
 hyperthermophilic eubacteria, 2:161–162
 iron–sulfur (FeS) protein biogenesis
 hydrogenases, 2:663
 iron–molybdenum cofactor (FeMo-co), 2:659f, 2:663
 ISC (iron–sulfur cluster) system
 assembly machinery, 2:662, 2:662f
 nitrogenases, 2:663
 nitrogen fixation (NIF) system, 2:663
 sulfur mobilization machinery, 2:662–663
 lectins, 2:701, 2:702f, 2:702t, 2:704t
 membrane-associated energy transduction, 2:204–209, 3:28–35
 adenosine diphosphate (ADP) phosphorylation, 2:204, 2:205f
 background information, 3:28
 catabolic reactions, 2:204
 energy-transducing functions
 anaerobic respiration, 2:206–208, 2:207f, 2:208f, 3:29, 3:29t, 3:30f, 3:31f
 basic concepts, 3:29–30
 denitrification, 3:29–30
 dicarboxylic acid decarboxylation, 2:208, 2:208f
 electrogenic transport, 2:208–209, 2:209f
 electron transport phosphorylation, 2:206–208, 2:207f, 2:208f
 fermentations, 3:29
 ferric iron reduction, 3:30
 fumarate respiration, 3:30, 3:30f
 H⁺ potential generation, 2:208–209, 2:209f
 H⁺ translocation, 2:206–208, 2:208f
 redox reactions, 2:206–208, 2:207f, 2:208f
 schematic diagram, 3:29f, 3:31f
 Na⁺ translocation, 2:206–208, 2:208f
 sulfur respiration, 3:30
 evolutionary development, 3:34
 oxygen respiration
 aerobic chemolithotrophs, 3:31–32
 aerobic organotrophs, 3:30–31, 3:31f
 phototrophic bacteria
 anoxygenic photosynthesis, 2:209, 2:335, 3:32, 3:693–694, 3:694f, 4:81
 antenna complexes, 3:32, 3:484, 3:484f
 evolutionary development, 3:34
 general discussion, 3:32
 oxygenic photosynthesis, 3:32
 plasma membranes, 3:28
 proton potential, 2:204, 2:205f, 2:206–208
 secondary energy transducers, 3:34
 mesophilic/psychrophilic eubacteria, 2:161
 messenger RNA (mRNA) decay, 3:52–58
 basic concepts, 3:52
 gene expression regulation, 3:56–57, 3:57f
 model comparisons, 3:54f, 3:56
 ribonucleases
 degradosome complex, 3:53
 3'-to-5' exoribonucleases, 3:53–55, 3:54f
 5'-to-3' exoribonucleases, 3:56
 3' exoribonucleases, 3:56
 oligonucleotides, 3:56
 phosphorolysis versus hydrolysis, 3:53–55, 3:55f
 poly(A) polymerase (PAP)-mediated decay, 3:54f, 3:55
 polynucleotide phosphorylase (PNPase), 3:53–55, 3:54f, 3:55f, 3:56–57, 3:57f
 ribonuclease E (RNase E), 3:52–53, 3:53t, 3:54f, 3:56–57, 3:57f
 ribonuclease G (RNase G), 3:53
 ribonuclease III (RNase III), 3:56–57, 3:57f
 ribonuclease J1 (RNase J1), 3:56
 ribonuclease J (RNase J), 3:55–56
 ribonuclease Y (RNase Y), 3:56
 small RNAs (sRNAs), 3:57, 3:57f, 4:249–250
 tmRNA system, 3:58
 translation processes, 3:57–58
 metabolic pathways, 4:249–250
 multidrug resistance (MDR) membrane proteins, 3:214
 non-homologous end joining (NHEJ)
 action mechanisms, 3:267–268, 3:267f
 characteristics, 3:266
 functional role, 3:268
 Ku protein, 3:266–267
 ligase D (LigD), 3:267
 viral infections, 3:268
 nuclear factor kappa B (NF-κB), 3:303t
 periplasmic electron-transport systems, 3:400–406
 complex-independent electron transfer, 3:404
 formate dehydrogenase, 3:402–403, 3:403f
 hydrogenases, 3:403
 iron (Fe(III)) respiration, 3:405
 Mitchellian redox loop mechanism, 3:400–404, 3:402f
 multiheme *c*-type cytochromes, 3:404–405, 3:404f
 nitrate reductase A, 3:403–404, 3:403f
 periplasmic nitrate reductase (Nap), 3:403f, 3:404
 respiratory chain complex III (ubiquinol cytochrome *c* reductase), 3:400, 3:401f
 synthesis, 3:405
 phosphatidylinositol-3-phosphate (PtdIns (3)P), 3:449
 phospholipase D (PLD), 3:473
 phototrophic bacteria
 anoxygenic photosynthesis, 2:209, 2:335, 3:32, 3:693–694, 3:694f
 antenna complexes, 3:32, 3:484, 3:484f
 evolutionary development, 3:34
 general discussion, 3:32
 oxygenic photosynthesis, 3:32, 4:81
 respiration, 4:79–82
 electron transport chains, 4:79, 4:80f
 genetic regulatory networks, 4:80–81, 4:80f
 metabolic characteristics, 4:79
 oxygenic photosynthesis, 4:81
 respiratory chain interactions, 4:79–80
 protein degradation
 adenosine triphosphate (ATP)-dependent proteases, 3:623–624
 functional role, 3:623
 substrate selection, 3:624
 pterin distribution, 3:666
 purple bacteria
 anoxygenic photosynthesis, 2:209, 3:32
 antenna complexes, 3:32
 electron acceptors and donors, 3:693–699
 cytochrome *cbh3* oxidase, 3:694f, 3:697, 3:697t, 4:79, 4:80f
 cytochromes, 3:695–696
 hydrogen (H), 3:698
 nicotinamide adenine dinucleotide dehydrogenase, 3:696
 nitrogen compounds, 3:698, 3:698t
 oxidases, 3:697–698

bacteria (*Continued*)

- photosynthetic reaction centers, 3:696–697, 3:696f
- quinol oxidase, 3:694–695, 3:694f, 3:695f, 3:697–698
- respiratory chain complex III (ubiquinol cytochrome *c* reductase), 3:695
- succinate dehydrogenase, 3:694f, 3:696
- sulfur compounds, 3:698, 3:698t
- electron transport chain
 - anoxygenic photosynthesis, 3:32, 3:693–694, 3:694f
 - membrane transport, 3:693–695
 - RegA/RegB regulation, 3:695, 3:695f
 - respiration, 3:694–695, 3:694f
- evolutionary development, 3:34
- general discussion, 3:32
- metabolic characteristics, 3:693
- oxygenic photosynthesis, 3:32
- photosynthetic reaction centers, 3:700–707
 - anoxygenic photosynthesis, 3:693–694, 3:694f
 - characteristics, 3:700
 - cytochrome *c*₂ oxidation, 3:706–707, 3:706f
 - intramolecular electron transfer, 3:705
 - kinetic mechanisms, 3:703
 - molecular characterization, 3:700–702, 3:702f
 - mutagenesis, 3:705
 - oxidation–reduction potentials, 3:703
 - photosystem II (PSII) complex, 3:707
 - quinone reduction and protonation, 3:704f, 3:706
 - substrate analog and inhibitor complexes, 3:703–705, 3:704f
 - subunit structure and functions, 3:700–702, 3:701f
 - X-ray crystallographic structure, 3:702–703
- recombination-dependent DNA replication (RDR), 4:24
- reductive reactions, 1:486, 1:487t
- regulated intramembrane proteolysis (RIP)
 - cAD1 precursor, 4:51f, 4:52–53
 - RseA, 4:51f, 4:52
 - SpolVFB protein, 4:51f, 4:53
- retrotransposons, 3:283, 3:284f
- ribonucleic acid (RNA)
 - ribosomal RNA (rRNA), 3:554–560
 - Bacillus subtilis*, 3:558–559
 - characteristics, 3:554
 - defective processing consequences, 3:559
 - Escherichia coli*, 3:557–558
 - maturation processes, 3:556, 3:557f
 - proteobacteria, 3:559
 - quality control mechanisms, 3:559–560
 - transcript structure, 3:556, 3:557f
 - RNA polymerases, 2:366t
 - transfer RNA (tRNA), 3:554–560
 - characteristics, 3:554
 - defective processing consequences, 3:559
 - 5'-end–RNase P process pathway, 3:555, 3:555f
 - maturation processes, 3:554, 3:555f
 - quality control mechanisms, 3:559–560
 - structural characteristics, 3:554–555
 - 3'-end–RNase process pathway, 3:555–556, 3:555f
- RNA-binding attenuation protein (TRAP)-mediated transcription attenuation, 2:364
- RNA polymerases, 4:167–172, 4:173–184
 - antibiotic inhibition, 4:171–172, 4:171f
 - core enzyme structure
 - characteristics, 4:174–176, 4:174f
 - conformational flexibility, 4:176
 - domain structures, 4:175–176, 4:175t
 - nonconserved domains, 4:174f, 4:176
 - RNAP channels, 4:175–176
 - elongation complex structure
 - active center rearrangements, 4:180–182, 4:181f
 - catalytic sites, 4:181f, 4:182–183
 - general characteristics, 4:180–183
 - nucleotide addition cycle (NAC), 4:181f, 4:183
 - protein–DNA/RNA interactions, 4:180, 4:181f, 4:182t
 - structural organization, 4:180, 4:181f
 - translocation mechanisms, 4:181f, 4:183
 - enzymatic activities, 4:173
 - future research outlook, 4:183–184
- holoenzyme-promoter DNA complexes
 - closed promoter complex (R_Pc), 4:178f, 4:179, 4:179t
 - open promoter complex (R_Po), 4:178f, 4:179–180, 4:179t
 - structural characteristics, 4:178f, 4:179–180
- holoenzyme structure, 4:176–178, 4:177f
- nucleotide addition cycle (NAC), 4:170–171
- proofreading processes, 4:170–171
- subunit composition, 4:173
- transcription cycle
 - basic concepts, 4:167, 4:168f
 - elongation phase, 4:168f, 4:169–170, 4:173–174
 - initiation phase, 4:167–169, 4:168f, 4:173–174
 - Rho-mediated termination, 4:168f, 4:170
 - sigma(σ)-factors, 4:167–169, 4:168f
 - termination phase, 4:168f, 4:170, 4:173–174
- Tth* σ70 holoenzyme
 - core interactions, 4:176–178, 4:178f
 - domain structures, 4:176–178, 4:177f
 - general characteristics, 4:176–178
 - structural characteristics, 4:176, 4:177f, 4:178f
- selenoprotein synthesis
 - anticodon loop, 4:210, 4:211f
 - general discussion, 4:210–213
 - selenocysteine biosynthesis
 - basic concepts, 4:210–212
 - biosynthetic pathway, 4:211f
 - selenocysteine synthase (SelA), 4:210–211, 4:211–212, 4:211f
 - selenocysteine synthase (SelB)–guanosine triphosphate (GTP)–selenocysteyl-tRNA–selenocysteine insertion sequence (SECIS) element formation, 4:212, 4:213f
 - transfer RNA (tRNA)^{Sec}, 4:210, 4:211f
 - UGA codons
 - ribosomal-level decoding, 4:212–213
 - selenocysteine insertion sequence (SECIS) element, 4:213
 - selenocysteine specificity, 4:213
 - stop codons, 4:212
- site-specific recombination systems, 1:1
- small RNAs (sRNAs), 4:249–255
 - characteristics, 4:249–250
 - cis-acting riboswitches
 - characteristics, 4:250–251
 - RNA ligand sensors, 4:250f, 4:251
 - RNA thermosensors, 4:250, 4:250f
 - cis-encoded RNAs, 4:251, 4:252f
 - nucleic acid-binding protein (NABP), 4:252–253, 4:252f
 - protein modulation, 4:252–253
 - research summary, 4:255
 - trans-encoded RNAs, 4:251–252, 4:252f
- sugar transport, 2:387–390
 - ATP-binding cassette (ABC) transport systems
 - classification, 2:389
 - components, 2:389–390
 - functional role, 2:390
 - maltodextrin/maltose transport (MalEFGK₂), 2:390, 2:390f
 - structural characteristics, 2:389–390, 2:390f
 - background information, 2:387
 - electrochemical cation-gradient-driven symporters
 - classification, 2:388
 - functional role, 2:388
 - lactose permease (LacY), 2:388–389
 - melibiose permease (MelB), 2:389
 - sodium/galactose transport (SgIT), 2:389
 - structural characteristics, 2:388, 2:389f
 - phosphotransferase system (PTS)
 - classification, 2:387
 - components, 2:387, 2:388f
 - functional role, 2:387, 2:388f
 - preferential glucose utilization, 2:387–388
- transcription termination
 - characteristics, 4:407–410
 - elongation complex, 4:408f
 - factor-dependent termination
 - antitermination, 4:410

- elongation factors, 4:168*f*, 4:169–170, 4:409–410
- general discussion, 4:409
- Mfd-mediated termination, 4:409
- regulated termination, 4:410
- Rho-mediated termination, 4:168*f*, 4:170, 4:409
- transcription-coupled DNA repair, 4:409
- hairpin formation, 4:407–409, 4:408*f*
- intrinsic termination, 4:407–409, 4:408*f*
- translation elongation, 4:418–424
 - fidelity, 4:423
 - 50S ribosomal subunit, 4:419–420, 4:420*f*
 - peptidyltransferase center (PTC), 4:419, 4:420*f*
 - protein biosynthesis elongation
 - characteristics, 4:420–423
 - elongation phase, 4:421–423, 4:421*f*
 - initiation phase, 4:420–421, 4:421*f*
 - recycling phase, 4:421*f*, 4:423
 - termination phase, 4:421*f*, 4:423
 - regulation mechanisms, 4:423
 - research summary, 4:423–424

- batrachotoxin, 4:568*t*
- Batten disease, 4:507*t*
- Bax family, 1:165, 1:166*f*
- BbvCI enzyme, 2:131, 2:132*t*
- bc*₁ complex, 1:593–598

*bc*₁ complex (Continued)

action mechanisms
 inhibitors, 1:598
 proton conduction pathways, 1:597–598, 1:597f
 protonmotive Q cycle, 1:596–597, 1:597f, 3:663–664, 3:664f
 anoxygenic photosynthesis, 3:694f
 background information, 4:98
 basic concepts, 1:593
 biochemical free radical chain reactions, 3:170f, 3:172f, 3:173f
 cytochrome *c* interactions, 1:601, 1:601f
 electron transfer complexes, 3:695, 4:93f
 facultative phototrophic respiration, 4:79, 4:80f
 functional role, 1:593, 1:594f, 4:84
 green sulfur bacteria, 1:601f, 2:511f
 mitochondrial ROS, 4:19f, 4:20
 oxygen respiration, 3:30–31
 periplasmic electron-transport systems, 3:400, 3:401f
PET genes, 3:308f
 photosynthesis/respiration, 3:695
 photosynthetic reaction centers, 3:693–694, 3:694f, 3:701f
 plant mitochondrial electron transport chain, 1:145, 1:146f
 protein subunits, 1:593–594
 protonmotive electron transfer chain, 1:470–471, 1:470f
 quinone pool functions, 3:695f
 respiratory electron transport chain, 3:661–662, 3:662f, 3:663–664, 3:664f, 3:694–695, 3:694f, 4:79, 4:80f
 schematic diagram, 4:84f, 4:99f
 spectroscopic properties, 1:594–596, 1:595f
 structural characteristics, 1:596, 1:596f
 thermodynamic properties, 1:595–596, 1:595f

B cells
 B-cell antigen receptors (BCRs), 1:161–164
 antibody–antigen interactions, 1:162
 class switching, 1:163
 diversity mechanisms, 1:161–162
 domain structures, 1:161, 1:162f
 downstream signaling events, 1:162–163, 1:163f
 early signaling events, 1:162, 1:163f
 functional role, 1:161
 gene transcription regulation, 1:162–163, 1:163f
 immune responses, 1:163
 immunoglobulin α (Ig α), 1:161, 1:162, 1:163f
 immunoglobulin β (Ig β), 1:161, 1:162, 1:163f
 immunoreceptor tyrosine-based activated motifs (ITAMs), 1:162, 1:162f, 1:163f
 research summary, 1:163
 signaling pathways, 1:162
 somatic hypermutation, 1:163
 DNA mismatch repair (MMR), 2:64–65
 G₁₂/G₁₃ family functions, 2:345t
 hematopoiesis, 1:188f

immunoglobulin Fc receptors (FcRs), 2:569–571
 lectins, 2:705
 nicotinic acid adenine dinucleotide phosphate (NAADP)-induced calcium ion (Ca²⁺) release, 2:638, 2:638t
 protein tyrosine phosphatase (PTP), 3:649–651, 3:651t
 tumor necrosis factor receptors (TNFRs), 4:459
 V(D)J recombination, 3:272, 3:272f
 BceSI enzyme, 2:137t
 Bcgl enzyme, 2:131, 2:132t, 2:133–134
 Bcl10 family, 4:377–378
 Bcl2 family, 1:165–166
 Bcl2 homology (BH) domains, 1:165, 1:166f
 BH3-only proteins, 1:165, 1:166f, 1:389f
 biochemical free radical chain reactions, 3:173f
Caenorhabditis elegans programmed cell death, 1:165
 cell death inhibitors, 1:165, 1:389f, 1:390f
 family classifications, 1:165, 1:166f
 mitochondrial permeability transition pore, 3:165–166
 mitochondrion-dependent apoptosis, 3:174
 therapeutic uses, 1:165–166
 BCS1 clade, 1:3t, 1:4, 1:4f
 B-DNA (antiparallel right-handed double helix), 2:142
 beans, 4:533t
 Becker muscular dystrophy, 2:471t, 2:474–475
 beef, 4:533t
 beetles, 4:516t
 beets, 2:638t
Belgica antarctica, 2:590–591
 Benson–Calvin cycle
 chloroplasts, 1:507, 1:511–512, 1:512f
 photosynthetic carbon dioxide (CO₂) fixation, 3:494, 3:494f, 3:495f
 benzo[a]pyrene, 3:330t
 benzoate
 medium-chain acyl-CoA synthetase (MCAS), 2:292
 urea cycle, 4:495f
 benzodiazapine, 2:347, 2:348f, 2:722, 2:723–724, 2:725, 2:725f
 benzoquinones
 catecholamine-derived *o*-benzoquinones, 3:727, 3:727f
 chemical characteristics, 3:722–723
 coenzyme Q
 biosynthesis, 3:726f, 3:727
 chemical characteristics, 3:723–724
 functional role
 antioxidant actions, 3:725–727
 electron transfer mechanisms, 3:724–725, 3:724f, 3:725f
 plasma membrane oxidoreductase, 3:725
 Q-cycle, 1:511–512, 3:725, 3:725f
 homologs and analogs, 3:723–724, 3:723t

benzosemiquinones, 3:722–723
 benzyladenine, 1:627, 1:628f
 benzylamine, 3:187f
 benzylamine oxidases, 1:89
 beriberi, 1:202, 1:208
 BES1/BZR1 (bri1-ethylmethane sulphonate suppressor 1/brassinazole-resistant 1), 1:253f, 1:254
 beta adrenergic receptors
 feedback regulation, 1:578–579, 1:578f
 general characteristics, 1:59
 pharmacological/molecular characteristics, 1:59
 schematic diagram, 1:58f
 β -alanin, 3:717–718, 3:717f
 β -aminoisobutyric acid, 3:717–718, 3:717f
 β -arrestins, 4:363–364, 4:363f
 β -carbolines, 2:723–724, 2:724f
 β -carotene
 antioxidant actions, 2:77
 cytochrome *b₆* complex, 4:337f, 4:338
 molecular structure, 1:502f
 β -catenins, 1:53–54, 1:53f
 β -galactosidases, 2:77, 4:291
 β -globin genes, 2:109
 β -glucocerebrosidase, 4:291–292
 β -helix proteins, 2:176
 β -hydroxybutyrate
 cerebral metabolism, 1:371–373
 mitochondrial permeability transition pore, 3:164
 starvation, 4:298–299, 4:302, 4:302f, 4:303–304, 4:305
 β -methylcrotonoyl-coenzyme A (CoA) carboxylase, 1:221, 2:386
 β -oxidation
 fatty acid synthesis pathway, 2:276f, 2:291f
 gluconeogenesis, 2:381
 mitochondrial acyl-CoA/CoA ratio regulation, 1:387
 mitochondrial β -oxidation
 carnitine-dependent cellular uptake and activation, 1:384–385, 1:385f
 mitochondrial carnitine system, 1:385–386
 reaction pathways, 1:386, 1:386–387
 peroxisome proliferator-activated receptor alpha (PPAR α), 3:419–421, 3:420f
 thiamine diphosphate (ThDP), 1:207f
 β -site APP cleaving enzyme (BACE), 4:200–201, 4:201f
 β sliding clamp, 2:54–56, 2:55t, 2:56f
 betaglycan, 1:232, 1:232t
 betaine, 2:722, 2:723f
 betaine homocysteine methyltransferase (BHMT), 2:325f, 2:326
 [BETA] prion, 3:566
 Bethlem myopathy, 3:167
 BIBN4096BS nonpeptide antagonist, 1:265, 1:266f
 bicarbonate, 1:46t, 3:514
 bicuculline, 2:723–724
 BIG protein family, 1:135–136, 1:135f
 bilateral adrenal hyperplasia, 1:584
 bile acids
 cholesterol biosynthetic pathway, 1:517f

- digestion and absorption, 2:358
 peroxisomal metabolic functions, 3:416
 very long-chain acyl-CoA synthetase (VLCAS), 2:293
- bile canaliculi, 1:190–191, 1:191f
- bile salts, 1:167–171
- biochemistry
 bile salt pool, 1:169–170
 biosynthetic pathway, 1:168–169, 1:168f
 characteristics, 1:167–170
 chemical components, 1:169–170
 chemical properties, 1:169
 transport and metabolism regulation, 1:169f
- functional roles, 1:167
- hepatic transport
 characteristics, 1:170
 cholestasis, 1:170
 physiological hepatocellular bile salt transport, 1:170
- therapeutic utilization, 1:170
- bilirubin, 3:547–549, 3:548f
- bi-molecular fluorescence complementation (BiFC), 2:749, 2:753f, 2:754
- bimolecular nucleophilic substitution (S_N2), 2:9
- BIN2 (BRASSINOSTEROID INSENSITIVE 2) kinase, 1:253f, 1:254
- binding immunoglobulin protein (BiP), 1:291t, 1:292–293
- biocuration, 3:616
- biocytin, 1:226
- bioenergetics
 bacteria
 ATP synthesis, 1:486–487, 1:487f
 growth categories, 1:488
 reductants, 1:487, 1:487f, 1:488f, 1:488t
 terminal electron acceptor (TEA), 1:487, 1:487t
 basic concepts, 1:217–220
 general discussion, 1:217
 mitochondrial respiration rate, 1:219–220
 proton circuit, 1:219–220, 1:219f
 thermodynamics
 adenosine triphosphate (ATP) synthesis, 1:218
 bioenergetic interconversions, 1:219
 Gibbs free energy, 1:217–218, 1:218f
 ion electrochemical potential differences, 1:219
 open systems versus closed systems, 1:217–219
 photons, 1:219
 redox reactions, 1:218–219
 glycerolipid synthesis, 2:415
 mitochondrial channels, 3:127
- bioflavonoids, 2:167–168
- BIOGRID database, 3:615t
- bioluminescence, 1:461–466
 definition, 1:461
 intracellular calcium ion (Ca^{2+}) indicators, 2:577, 2:577f
- luciferases
 bacterial luciferase, 1:464, 1:465f
 firefly luciferase, 1:462–465, 1:464f, 2:290–291
Vibrio fischeri, 1:465
- biomass-produced renewable hydrogen, 4:72–75
 background information, 4:72
 challenges, 4:74–75
 future research areas, 4:75
 organisms and fermentation pathways
 dark fermentation, 4:73–74, 4:74f, 4:75f
 photofermentation, 4:74, 4:75f
 process mechanisms, 4:74–75, 4:75f
 redox enzymes
 characteristics, 4:72–73
 hydrogenases (H_2 ases)
 [FeFe]-hydrogenases, 4:72, 4:73f, 4:74f
 [NiFe]-hydrogenases, 4:72–73, 4:73f, 4:74f
 nitrogenases, 4:73
 substrates, 4:73
- bioppterin
 biosynthesis, 3:666–667
 structural characteristics, 3:668f
- biotin, 1:221–225
 biotin acceptor peptides (BAPs), 1:64–65
 biotin domains
 characteristics, 1:222–223
 sequence alignment, 1:223f

 therapeutic outlook, 1:395f

caspases (*Continued*)

caspase 2

- action sequences, 1:391–392
- caspase knockouts, 1:392*t*
- classifications, 1:388–389
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392*t*
- phylogenetic relationships, 1:390*f*
- sequential activation, 1:393*f*

caspase 3

- action sequences, 1:391–392
- caspase knockouts, 1:392*t*
- classifications, 1:388–389
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392*t*
- phylogenetic relationships, 1:390*f*
- regulatory mechanisms, 1:390*f*
- sequential activation, 1:393*f*
- therapeutic outlook, 1:395*f*

caspase 4

- classifications, 1:388–389
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392*t*
- phylogenetic relationships, 1:390*f*

caspase 5

- classifications, 1:388–389
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392*t*
- phylogenetic relationships, 1:390*f*

caspase 6

- action sequences, 1:391–392
- caspase knockouts, 1:392*t*
- classifications, 1:388–389
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392*t*
- phylogenetic relationships, 1:390*f*
- regulatory mechanisms, 1:390*f*
- sequential activation, 1:393*f*
- therapeutic outlook, 1:395*f*

caspase 7

- action sequences, 1:391–392
- caspase knockouts, 1:392*t*
- classifications, 1:388–389
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392*t*
- phylogenetic relationships, 1:390*f*
- regulatory mechanisms, 1:390*f*
- sequential activation, 1:393*f*

caspase 8

- activation mechanisms, 1:394
- caspase knockouts, 1:392*t*, 1:393
- characteristics, 1:388–389
- downstream activators, 1:393, 1:394*f*, 4:377–378
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392*t*
- phylogenetic relationships, 1:390*f*
- regulatory mechanisms, 1:390*f*
- sequential activation, 1:393*f*

caspase 9

- action sequences, 1:391–392
- caspase knockouts, 1:392*t*
- classifications, 1:388–389
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392*t*
- phylogenetic relationships, 1:390*f*

- regulatory mechanisms, 1:390*f*
- sequential activation, 1:393*f*
- therapeutic outlook, 1:395*f*

caspase 10

- action sequences, 1:391–392
- classifications, 1:388–389
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392*t*
- phylogenetic relationships, 1:390*f*
- sequential activation, 1:393*f*

caspase 11, 1:392*t*

caspase 12

- classifications, 1:388–389
- phylogenetic relationships, 1:390*f*
- caspase knockouts, 1:392*t*, 1:393, 1:394*f*
- classifications, 1:388–389, 1:390*f*
- domain structures, 1:389, 1:393*f*
- downstream activators, 1:393, 1:394*f*, 4:377–378
- historical research, 1:388–389
- inhibitors of apoptosis proteins (IAPs), 1:391*t*, 1:392–393, 1:392*t*, 1:590
- molecular structure, 1:590*f*
- neurotrophins, 3:241–243, 3:242*f*
- phylogenetic relationships, 1:390*f*, 1:589
- signaling mechanisms, 1:394*f*, 1:618*f*, 4:457–458, 4:458*f*
- substrate recognition, 1:389–390, 1:391*t*, 1:393*f*

castanospermine (CSN), 2:459*f*castor beans, 2:702*t*catabolic hormones, 1:95–96, 1:96*f*, 1:150*t*

catabolite receptor protein (CRP)–cAMP complex, 2:387–388

catabolite repressor protein (CRP)

- functional role, 2:698–699
- historical research, 2:695
- schematic diagram, 2:695*f*
- structural characteristics, 2:697*f*, 2:699

catalases

- action mechanisms, 2:536, 2:536*f*
- functional role, 2:536, 3:407
- heme peroxidases, 3:407–409, 3:408*f*
- oxygenases, 2:536
- structural characteristics, 2:536

cataplerotic pathways, 4:305

cataracts, 2:632*t*

catecholamines

- amino acid metabolism, 1:93*t*
- catecholamine-derived *o*-benzoquinones, 3:727, 3:727*f*

epinephrine

- branched-chain amino acid (BCAA) regulation, 1:245–246
- characteristics and functional role, 1:57
- starvation effects, 4:303–304

norepinephrine

- ascorbic acid, 4:531–532
- characteristics and functional role, 1:57
- pancreatic endocrine cells, 2:596
- starvation effects, 4:302–303

catechol-*O*-methyltransferase (COMT), 1:57catenanes, 2:162, 2:162*f*

catenins

- α -catenins
- adaptor proteins, 1:258*f*

- cadherin signaling, 1:261, 1:262*f*
- characteristics, 1:255
- gene deletion effects, 1:259*t*

 β -catenins

- adaptor proteins, 1:258*f*
- adipocyte development, 1:53–54, 1:53*f*

calcitonin peptide family, 1:270–271
calcium-sensing receptor (CaSR), 1:326–328, 1:327f
calpains, 1:354–359
carboxyl methylation, 3:608–609, 3:608f
chemokine receptors
ligand binding, 1:480–482, 1:482f
subfamily classifications, 1:480
- C-terminal domain
AAA (ATPases associated with various cellular activities) proteins, 1:1–2, 1:2f
actin depolymerizing factor (ADF)/cofilin (ADF-H) domain, 1:23–24
alternative oxidases (AOXs), 1:146–147, 1:147f
alternative splicing, 1:76
arrestins, 2:489–490, 2:489f
ATP synthase, 2:271–272, 2:273f
bullous pemphigoid antigen 1 (BPAG1), 2:626f, 2:628–629
c-fes proto-oncogene (Fes), 1:451, 1:452f
copper-transporting ATPases (copper pumps), 3:672–673, 3:672f
cyclic adenosine monophosphate (cAMP) receptors (cARs), 1:562–563, 1:563f, 1:564
cyclic nucleotide-dependent protein kinases, 1:576f, 1:577–578
cytoplasmic dynein, 2:185–186, 2:186f
degradosome complex, 3:53
diaphanous autoinhibitory domain (DAD), 1:24
DNA gyrase, 2:164–165, 2:165f
DNA ligases, 2:30–31, 2:33, 2:34f
DNA polymerase III holoenzyme, 2:93
DNA-strand transferases, 4:37–38, 4:37f
elongation cycle, 2:253
glucokinase glucose sensors, 2:601f
glycine receptors (GlyRs), 2:421, 2:422f
glycoprotein hormone receptors, 4:388, 4:389f
hexameric enzyme helicases, 2:23f
initiation factors
initiation factor 1 (IF1), 4:427, 4:428f
initiation factor 2 (IF2), 4:428–430, 4:428f
initiation factor 3 (IF3), 4:428f, 4:430
inositol requiring 1 (IRE1) genes, 4:489, 4:490f
inositol triphosphate (IP₃), 2:586, 2:587f, 2:653–655, 2:654f, 2:655f
intermediate filaments, 3:233
iron–sulfur clusters (FeS), 4:95
keratins, 2:667
kinesin superfamily proteins (KIFs), 2:673f, 2:680
Kyprides–Onzonis–Woese (KOW) motif, 4:169–170
LacI protein, 2:697f, 2:698
LexA regulatory protein, 2:707–708, 2:707f
metabotropic glutamate (mGlu) receptors, 2:396, 2:396f
mitochondrial DNA (mtDNA), 2:7
MutY repair pathway, 2:58
neurofilament triplet proteins (NFTPs), 2:634
nuclear factor kappa B (NF-κB), 3:302
ORAI proteins, 3:362–363, 3:363f, 3:365f
parathyroid hormone (PTH)/PTH-related protein (PTHrP) receptor (PPR), 3:386–387
phosphatidic acid phosphatases (PAPs), 1:661f, 1:662
phosphodiesterases (PDEs), 1:581, 1:581f
photosystem I (PSI) complex, 3:503–505, 3:504f
plasma membrane calcium (Ca²⁺)-ATPase pump, 3:525–526, 3:526f
plasma membrane proton (H⁺)-ATPases, 3:688–689, 3:690–691
platelet-activating factor receptor (PAFR), 3:534–535
platelet-derived growth factor (PDGF), 3:538, 3:539f
plectin, 2:625, 2:626f
polymerase α-primase (Pol α), 2:241–242
polymerase δ (Pol δ), 2:246f
polymerase η (Pol η), 4:573–574, 4:573f
prion domains, 3:566–567, 3:568f
protein kinase B (PKB), 3:463–464
PsaC protein, 2:340, 2:340f
P-type adenosine triphosphatase (ATPase), 4:330–331, 4:330f
Ras proteins, 4:12, 4:13f
replication focus targeting sequence (RFTS), 3:8–9, 3:8f
retinoblastoma protein (pRB), 4:105
RNA polymerase II (Pol II)
characteristics, 2:365
initiation phase, 2:366, 3:63–64, 3:63f
3'-end maturation, 3:189–191, 3:190t
transcription cycle, 2:365, 3:63–64, 3:63f
transcription termination, 2:367, 3:63–64, 3:63f
RNA polymerase domain structures, 4:175–176, 4:175t, 4:177f
ryanodine receptors (RyRs), 4:196
serine recombinases, 1:558–559
sliding clamps, 2:114–115, 2:115f, 3:576, 4:237–238
small guanosine phosphatases (GTPases), 4:242, 4:244f
store-operated Ca²⁺ entry (SOCE), 3:364, 3:365f
stromal-interacting molecule (STIM) protein family, 4:315, 4:316f
T7 RNA polymerase
polymerase sequence similarities, 4:355–357, 4:356f, 4:357f
structural characteristics, 4:355, 4:356f
structure–function relationship, 4:355, 4:357f
tubulin, 4:450–451, 4:451f
type IB DNA topoisomerase, 2:160, 2:160f
type I DNA restriction and modification enzymes, 2:72–73
type I DNA topoisomerase, 2:158, 2:159f
type XVII collagen, 1:641
tyrosine recombinases, 1:556–557, 1:557f
uncoupling proteins (UCPs), 4:483–484, 4:485f
vascular endothelial growth factor receptors (VEGFRs), 4:510, 4:510f
voltage-gated sodium channels, 4:564, 4:565f
xeroderma pigmentosum (XP), 4:574
C-terminal fragments (CTFs), 4:202
ferredoxin (Fd)
ferredoxin-NADP⁺ reductase (FNR)
structure, 2:299, 2:300f
ferredoxin structure, 2:296, 2:297f
iron–sulfur clusters (FeS), 4:95
gelsolin, 1:277–278, 1:277f
G_i family functions, 2:380
glycosylphosphatidylinositol (GPI)-anchored proteins, 2:476–477
histone H1, 1:531
integrin signaling, 2:608
lipid-modified proteins
glycosylphosphatidyl inositol (GPI) anchors, 2:737t, 2:738
palmitoylation, 2:736–737
prenylation, 2:737–738, 2:737t, 3:608–609, 3:608f
major sperm protein (MSP), 3:1–2
microtubule-associated proteins (MAPs), 3:104–105, 3:105f
MutL pathway, 2:55–56
MutS pathway, 2:55
neurofilament triplet proteins (NFTPs), 2:634
nitric oxide synthase (NOS)
calmodulin (CaM)–nitric oxide synthase (NOS) interactions, 1:342–343
C-terminal extension, 1:344–346, 1:344t, 1:345f
olfactory receptors, 3:345–346
peptide amidation, 3:396
pheromone receptors, 3:441–442
presenilins, 4:202

C-terminals (*Continued*)

- proteasome activating nucleotidase (PAN), 3:599
- protein N-myristoylation, 3:642–643, 3:643f
- protein tyrosine phosphatase (PTP), 3:651f
- respiratory chain complex I (NADH: ubiquinone oxidoreductase), 4:88
- retinoic acid receptors, 4:109
- Smad signaling, 1:232–233
- sodium ion/calcium ion ($\text{Na}^+/\text{Ca}^{2+}$) exchanger, 3:45f, 3:46–47
- Src (sarcoma) family kinases, 4:295–297, 4:296f
- tachykinins, 4:360–365
 - basic concepts, 4:360
 - hemokinin 1, 4:361, 4:361f
 - neurokinin-1 receptor (NK1R)
 - affective disorders, 4:364–365
 - carboxyl tail, 4:363–364, 4:363f
 - depression, 4:364–365
 - disease connections, 4:364–365, 4:364f
 - emesis, 4:364
 - full-length NK1R, 4:361–363, 4:362f
 - functional role, 4:361, 4:362f
 - glioblastomas, 4:365
 - truncated NK1R, 4:363
 - neurokinin A, 4:360–361, 4:361f, 4:364f
 - neurokinin B, 4:361, 4:361f, 4:364f
 - substance P, 4:360, 4:361f, 4:364f
 - toll-like receptors (TLRs), 4:397–398
 - ubiquitin interaction motif (UIM), 3:598
 - vasopressin/oxytocin family, 4:517–519
- Ctf4 coupling factor, 1:402t, 1:403f
- CTXφ genome, 1:558, 1:558f
- C-type lectin receptors (CLRs), 4:396
- C-type natriuretic peptide (CNP), 3:226, 3:226f
- cucumbers, 4:533t
- cullins, 4:470
- curcumin, 3:305, 3:305t
- currants, 4:533t
- Cushing's syndrome, 1:584
- CXXC domain, 1:523, 1:523f, 3:8–9, 3:8f
- cyan fluorescent proteins (CFPs), 2:751–752
- cyanide, 1:143t, 2:534
- cyanobacteria
 - δ-aminolevulinic acid (ALA) formation, 3:544
 - electron transport pathways, 4:81–82, 4:82f
 - ferredoxin-NADP⁺ reductase (FNR), 2:299
 - iron–sulfur (FeS) protein biogenesis, 2:663
 - light harvesting complexes, 2:726
 - membrane-associated energy transduction
 - anoxygenic photosynthesis, 2:209, 2:335, 3:32
 - antenna complexes, 3:32, 3:484, 3:484f
 - evolutionary development, 3:34

polymerase α -primase (Pol α), 2:119

polymerase δ (Pol δ), 2:120

polymerase ϵ , 2:120

proliferating cell nuclear antigen

(PCNA), 1:402t, 2:119

replication factor C (RFC), 2:120

replication protein A (RPA), 1:402t,
2:118–119, 2:119f

sliding clamps, 2:119

topoisomerases, 2:120

research summary, 2:113

functional role, 4:232

GAL promoter system, 1:525–529

chromatin regulation function

active (galactose-induced) state, 1:527

inactive states, 1:527–528

promoter nucleosomes–regulatory
factors interactions, 1:528–529

GAL1–10 gene expression

basic concepts, 1:525–527

gene-specific factors, 1:525–526

hypersensitive region (HR),
1:526–527, 1:526f

nucleosome positioning, 1:525

promoter chromatin organization,
1:526–527, 1:526f

promoter elements, 1:525, 1:526f

regulatory and transcription factors,
1:525–526

gene-specific factors

Gal3p, 1:525–526

Gal4p, 1:525, 1:528–529

Gal80p, 1:525, 1:528–529

global process factors, 1:526

promoter chromatin organization

GAL1–10 gene expression, 1:526–527,
1:526f

regulation function, 1:529

genetic information transfer, 4:185, 4:186f

helicases

bacterial DNA replication, 2:92, 2:93f,

2:94f, 2:115–116, 2:116t,

2:121–122, 2:122f

characteristics and functional role, 2:21,
3:261, 4:43

D-loop dissociation

enzyme disruption, 4:32–33

Holliday junction (HJ) dissolution,

4:30f, 4:33

Holliday junction (HJ) resolution,

4:30f, 4:33

resolvases, 4:30f, 4:32–33

DnaB–DnaC complex, 2:124

DnaB helicase, 2:21, 2:22, 2:22t,

2:25–26, 2:92, 2:93f, 2:94f, 2:116t,
2:124

DnaC helicase, 2:115–116, 2:116t,

2:123–124

DNA recombination

D-loop disruption, 4:32–33

enzyme translocation, 4:30–31, 4:30f,
4:31t

Holliday junction (HJ) dissolution,

4:33

Holliday junction (HJ) resolution,

4:33

recombination inhibitors, 4:33–34

recombination models, 4:30f

research summary, 4:34

single-strand DNA (ssDNA),
4:31–32

eukaryotic DNA replication, 2:118

hexameric enzyme action, 2:21–27

classifications, 2:21, 2:22t

double-strand DNA (dsDNA)

translocation, 2:24–25

loaders/loading process, 2:21–22,
2:22t

nucleoside triphosphatase (NTPase)-
powered translocation, 2:22–24,
2:24f

research summary, 2:26

single-strand DNA (ssDNA)

interactions, 2:21

structural characteristics, 2:21, 2:23f

unwinding mechanisms, 2:25–26,
2:25f

mismatch repair (MMR), 2:67, 2:67f

PcrA helicase

characteristics and functional role,
3:261

crystal structures, 3:262, 3:262f

DNA unwinding, 3:263–264

open and closed conformations,
3:262–263

primary structures, 3:261–262

research summary, 3:265

single-strand DNA (ssDNA)

translocation, 3:263, 3:264,
3:264f

translocase-based protein

displacement, 3:265

RecA helicases, 2:21, 2:22t, 4:32

RecBCD helicases, 4:32

RecB helicases, 4:32

RecD helicases, 4:32

recombination inhibitors, 4:33–34

Rep helicases

characteristics and functional role,
3:261

crystal structures, 3:262, 3:262f

DNA unwinding, 3:263–264

domain structures, 3:263f

- 7,8-dihydro-8-oxo-guanine (8-oxoG), 2:54
- dihydrobiopterin, 3:666–667, 3:668f
- dihydrofolate reductase (DHFR), 2:109–110, 2:325, 2:325f
- 24,25-dihydrolanosterol, 1:518f, 1:519
- dihydrolipoyl acetyltransferase, 4:321–322
- dihydrolipoyl dehydrogenase, 4:321–322, 4:324
- dihydroorotase (DHOase), 3:712, 3:713f, 3:714f
- dihydroorotate dehydrogenase (DHODH), 3:712, 3:713f, 3:714f
- dihydropyrimidine dehydrogenase (DPD), 3:717–718, 3:717f
- dihydrothymine, 3:330t
- dihydroxyacetone phosphate (DHAP), 2:415, 2:416f, 2:445f, 3:416–417, 3:499f
- dihydroxybenzene, 3:722–723
- dihydroxyphenylalanine (L-DOPA), 1:57, 2:173
- dihydrozeatin, 1:627, 1:628f
- dilated cardiomyopathy (DCM), 1:638t, 2:632t, 4:447–449, 4:448f
- dilated myocarditis, 3:117
- dimethylallyl pyrophosphate (DMAPP), 1:627–628
- 3,3-dimethyldioxirane (DMDO), 1:4f
- dimethylthiosulfonium triflate (DMTST), 1:4f
- dimethylsulfoxide (DMSO), 4:79, 4:80f
- dimethylsulfoxide reductase, 1:487t
- DinB homolog, 2:709–710, 4:480–481
- diol dehydratase, 1:156, 1:158t
- dioxygenases, 3:371–372
- dipeptidylpeptidase-4 (DPP-4), 1:116, 1:658
- 9, 10-diphenylanthracene, 1:463f
- 2,3-diphosphoglycerate (2,3-DPG), 2:534
- diplonema, 3:19, 3:19f, 3:22f
- disrupted-in-schizophrenia 1 (DISC1) protein, 1:197f, 1:199, 1:200f
- disulfide bond formation, 1:664–667
 basic concepts, 1:664, 1:665f
 catalytic reactions
 background information, 1:665
 protein disulfide isomerase (PDI), 1:665, 1:665f
 thioredoxin family, 1:665
 cellular environments
- extracellular proteins, 1:666, 1:667f
 regulatory mechanisms, 1:666
 thiol/disulfide redox environments, 1:666
- isomerization processes, 1:664, 1:665f
- molecular structure, 1:664, 1:665f

 basic principles, 1:664
 formation mechanisms, 1:664, 1:666f
 general discussion, 1:664
- disulfiram, 3:398
- ditercalinium complex, 3:330t
- diubiquitin, 4:471–472
- diversity-generating retroelements (DGRs), 3:284
- Dmc1 recombinase, 2:558, 2:559f, 4:37f
- dnaA* gene, 2:42
- DnaA helicase
 DNA unwinding, 2:121–122, 2:122f
 functional domains, 2:121–122, 2:122t
 replisome assembly process
 characteristics, 2:122–123
 DiaA protein stabilization, 2:123
 DnaA-dependent unwinding, 2:123
 DnaA-oriC complex formation, 2:122–123
 HU protein stabilization, 2:123
- DnaB–DnaC complex, 2:124
- DnaB helicase, 2:21, 2:22, 2:22t, 2:25–26, 2:92, 2:93f, 2:94f, 2:116t, 2:124
- DnaC helicase, 2:115–116, 2:116t, 2:123–124
- DNA Data Bank of Japan, 3:611–612, 3:615t
- DnaG helicase, 2:92, 2:93f, 2:116t
- DnaX complex, 2:95
- dnaX* gene, 2:95
- DOCK family proteins, 1:441f, 1:480–482, 4:111–112, 4:112f
- docosahexenoic acid, 2:288, 2:288f
- dogfish, 4:516t
- dolichols
 cholesterol biosynthetic pathway, 1:516, 1:517f
 dolichol phosphate (Dol-P), 2:457, 2:458f
 N-linked glycosylation, 2:457, 2:458f
- dolichyl pyrophosphate (Dol-P-P), 2:315–316, 2:315f, 2:316t
- Donnan potential, 3:161
- dopamine
 DARPP-32, 4:222f, 4:223
 dopamine β-hydroxylase, 1:57, 2:259, 2:259f
 dopamine receptors, 2:169–173
 calcium ion (Ca²⁺) signaling, 2:720f
 D1 and D2 receptor-selective drugs, 2:171
 receptor distribution, 2:172–173
 receptor signaling
 general discussion, 2:171–172
 G protein coupling, 2:171, 2:172t
 heterotrimeric G proteins, 2:171
 signaling pathways, 2:172
 receptor subtypes
 characteristics, 2:172t
 D1 and D2 subtypes, 2:169, 2:170f
 DNA sequences, 2:169–171, 2:170f

- general discussion, 2:169–171
 molecular cloning, 2:169–171, 2:170f
 receptor variants, 2:172t, 2:173
 research background, 2:169
 structural characteristics, 2:170f, 2:171
 therapeutic uses, 2:173
 monoamine oxidase, 3:187f
 synthetic pathways, 1:57
 transport mechanisms, 3:238–239
 doublecortin (DCX), 1:196–197, 1:197f
 double Holliday junction (DHJ), 2:558, 2:559f, 3:22f, 4:29, 4:30f, 4:46, 4:47f, 4:48f
double-sex (dsx) gene, 1:82, 1:82f, 1:85–86
 double-stranded RNAs, 3:98, 4:155–156, 4:156f
 Dovonex®, 4:539
 downstream regulatory element antagonist modulator (DREAM), 1:311, 1:313–314, 1:314f, 2:485t, 3:293, 3:295
 Down syndrome
 meiotic defects, 3:23
 tau proteins, 1:477t
 doxorubicin, 2:167, 2:167f
 Dpb11 loading factor, 1:401–402, 1:402t, 1:403f, 1:404f
 DPPY motif, 2:137–138, 2:137f
 DRIP complex, 4:543
Drosophila melanogaster
 actin-related proteins (Arps), 1:37f
 adenosine-to-inosine (A-to-I) RNA editing, 4:154–155
 alternative splicing-based sex
 determination regulation, 1:81–86
 aquaporin water channels, 1:125
 aspartic proteases, 1:137, 1:138f
 base excision repair (BER), 2:5t
 Bubblegum ACS family (ACSBG), 2:294
 calpains, 1:354f, 1:359
 carbohydrate-responsive element binding protein (ChREBP) distribution, 1:374
 cardiac muscle development, 1:183–185
 centromere region, 1:447t, 1:448f
 chromodomain helicase DNA binding (CHD)/Mi-2 family, 4:64
 classical zinc fingers, 4:577
 Csk protein kinase, 4:295–296
 DNA replication, 2:109–110
 EF-hand proteins, 1:319t
 endocrine regulation
 juvenile hormone (JH), 2:594
 prothoracicotropic hormone (PTTH), 2:594, 2:594f
 20-hydroxyecdysone (20E), 2:593, 2:593f
 focal adhesion kinase (FAK) family, 2:266f, 2:267–268
 G protein-coupled receptor kinases (GRKs), 2:483
 hexokinases, 2:544
 intracellular neutral lipid storage droplets, 1:47, 1:48f, 1:51
 IP₃ receptors (IP₃R), 2:653–655
 kinesins, 2:674
 kinesin superfamily proteins (KIFs), 2:679–681, 2:682f
 LacI-lamin protein, 3:315–316, 3:316f
 matrix metalloproteinases (MMPs), 3:90
 metabolomic research, 2:590
 microRNA (miRNA)-based lipid
 metabolism regulation, 4:192–193, 4:194t
 multiple-domain proteins, 3:628f
 olfactory receptors, 3:346
 ORAI protein family, 4:315
 origin recognition complex (ORC), 2:111
 P2Y receptors, 3:376–377
 parathyroid hormone (PTH)/PTH-related protein (PTHrP) receptor (PPR), 3:384
 peptide amidation, 3:398
 phospholipase D (PLD), 3:473–474
 platelet-derived growth factor (PDGF), 3:538
 protein palmitoylation, 3:645–646
 pterin distribution, 3:666
 recombination-dependent DNA
 replication (RDR), 4:25
 RecQ helicases, 4:43–44, 4:44f
 regulated intramembrane proteolysis (RIP)
 rhomboid-based mediation, 4:51f, 4:54
 sterol regulatory element binding protein (SREBP), 4:52
 retrotransposons, 3:283, 3:284f
 septin complexes, 4:214–215, 4:218
 sex determination
 double-sex (dsx) gene regulation, 1:85–86
 exon organization and splicing patterns, 1:81–82, 1:82f
 fruitless (fru) gene regulation, 1:85–86
 regulatory hierarchy, 1:81, 1:82f
 research summary, 1:86
 Sxl autoregulation, 1:82–84, 1:85f
 transformer (tra) gene regulation, 1:82, 1:85–86, 1:85f
 small RNAs (sRNAs), 3:98
 Src (sarcoma) family kinases, 4:297
 stromal-interacting molecule (STIM)
 protein family, 4:315, 4:316f
 sugar nucleotide transporters, 4:350
 SWItching defective/Sucrose NonFermenting (SWI/SNF) family, 4:63–64
 vitamin E metabolism, 4:549
 voltage-gated six-transmembrane K⁺ channels, 4:556–557
Drosophila simulans, 3:285f
Drosophila virilis, 3:285f
 dsRNA-binding motifs, 3:98, 4:155–156, 4:156f
 dual-specificity tyrosine phosphorylation-regulated kinase 2 (DYRK2), 1:312, 1:313f
 Duchenne muscular dystrophy, 2:471t, 2:474–475
 DUF 283 domain, 3:99–100
 dUTP pyrophosphatase (dUTPase), 2:2
 DWARF genes, 1:251
 dwarfism, 3:657t, 3:658
dwarf genes, 1:251, 1:252f
 dynein, 2:174–177
 binding activities
 cargo binding, 1:634, 2:175f
 cellular membranes, 2:177
 chromosomal kinetochores, 2:177
 cytoplasmic structures, 2:177
 general discussion, 2:176
 microtubule binding, 2:175f, 2:176–177, 2:176f
 motor binding, 2:175f, 2:176f, 2:177
 composition, 2:174, 2:175f
 functional roles
 dynein–dynactin complex
 adapter functions, 2:174–175
 dynein-based motility, 1:37f, 1:38t, 2:174
 processivity, 2:175
 dynein-independent functions, 2:175
 structural characteristics, 2:174, 2:175f
 subunit structure and functions
 actin-related/actin-binding proteins, 2:175
 β-helix proteins, 2:176
 dynamitin, 2:175–176, 2:175f
 elongated α-helical proteins, 2:175–176
 p150^{Glued protein}, 2:175–176, 2:175f, 2:176f
 p24 protein, 2:175–176, 2:175f
 p25 protein, 2:175f, 2:176
 p27 protein, 2:175f, 2:176
 p62 protein, 2:175f, 2:176
 RING/LIM domain protein, 2:175f, 2:176
 structural subfamilies, 2:175
 dynamin
 chemokine receptors, 1:483f
 clathrin-mediated endocytosis, 2:198, 2:198f
 dynamin related protein 1 (Drp1), 3:136–137, 3:137f
 nitric oxide synthase (NOS), 1:343–346
 dynamitin, 2:175–176, 2:175f
 dyneins, 2:184–187
 axonemal dyneins
 binding characteristics, 2:185t, 2:186–187
 inner arm dyneins, 2:185t, 2:187
 outer arm dyneins, 2:185t, 2:187
 characteristics and classifications, 2:184, 2:185t
 cytoplasmic dyneins
 cytoplasmic dynein 1, 2:185–186, 2:185t, 2:186f
 cytoplasmic dynein 2 (IFT dynein), 2:185t, 2:186
 kinesin superfamily proteins (KIFs), 2:684f
 cytoskeletal walking model, 1:632, 1:633f
 dynein–dynactin complex, 1:37f, 1:38t, 2:174, 4:208, 4:208f
 dynein heavy chain, 2:184–185, 2:185t, 2:186f
 dynein intermediate chain, 2:185t, 2:186f
 dynein light chain, 2:185t, 2:186f
 dysfunctional mitochondria, 3:173–174
 dyskeratosis congenita (DC), 4:121, 4:385
 dyskerin, 4:385
dystonia musculorum (dt), 2:628–629, 2:629t
 α-dystroglycan, 2:454f, 2:456, 2:474–475

dystrophic epidermolysis bullosa (DEB),
1:641t
dystrophin
 dystrophin–glycoprotein complex (DGC),
 2:474–475
 pectin, 2:625–627

E

- fermentation reactions, 2:205*t*
 ferredoxin-NADP⁺ reductase (FNR), 2:301
 fumarate respiration, 2:207*f*, 2:208*f*
 GroEL (growth E locus, large gene, bacterial group I chaperonin), 1:457–458, 1:458*f*, 1:459
 heme biosynthesis, 3:547
 heme-copper oxidases, 1:604*t*
 LacI-lamin protein, 3:315, 3:316*f*
lac operon
 catabolite repressor protein (CRP)
 functional role, 2:698–699
 historical research, 2:695
 schematic diagram, 2:695*f*
 structural characteristics, 2:697*f*, 2:699
 characteristics, 2:695–696
 historical research, 2:694–695
 lactose repressor protein (LacI)
 functional role, 2:696–697
 looped structures, 2:698, 2:698*f*
 pseudo-operator sequences, 2:698, 2:698*f*
 structural characteristics, 2:697–698, 2:697*f*
 research errors, 2:699
 schematic diagram, 2:695*f*
 transcription-coupled repair (TCR), 4:402
 lactose permease (LacY), 2:389*f*
 lectins, 2:702*f*, 2:702*t*
 LexA regulatory protein
 gene expression regulation, 2:706
 regulon characteristics, 2:706–707, 2:710
 repression mechanisms, 2:707–708, 2:707*f*
 SOS response, 2:706
 structural characteristics, 2:707*f*, 2:708*f*
 maltose-binding protein (MalBP), 1:62, 2:389–390
 membrane-associated energy transduction
 ferric iron reduction, 3:30
 oxygen respiration, 3:30–31
 messenger RNA (mRNA) decay
 degradosome complex, 3:53
 poly(A) polymerase (PAP)-mediated decay, 3:54*f*, 3:55
 ribonuclease E (RNase E), 3:52–53, 3:53*t*, 3:54*f*, 3:56–57, 3:57*f*
 ribonuclease G (RNase G), 3:53
 metalloproteases, 3:87–88
 mismatch repair systems (MRSs)
 anti-recombination activity, 2:47–48, 2:48*f*
 components, 2:42
 GO system (MutM–MutT–MutY), 2:80, 2:80*f*
 long-patch mismatch repair
 Dam methyltransferase, 2:54
 DNA polymerase III holoenzyme, 2:95
 drug resistance, 2:57
 excision and repair synthesis, 2:56
 initiation phase, 2:55–56
 mismatch repair deficiency, 2:57
 MutH pathway, 2:56, 2:56*f*
 MutL pathway, 2:55–56, 2:56*f*
 MutS pathway, 2:55, 2:56*f*
 process mechanisms, 2:54–56, 2:56*f*
 repair enzymes, 2:54–56, 2:55*t*, 2:56*f*
 specificity, 2:54
 methyl-directed MRS, 2:45–46
 Mut protein family, 2:66–68, 2:67*f*
 MutS–MutY interactions, 2:58
 MutY repair pathway, 2:57–58, 2:57*f*
 specificity, 2:54
 very-short patch (VSP) repair
 research background, 4:76
 vsr gene biochemistry, 4:76–77
 vsr gene mutagenesis, 4:77
 vsr gene structure and regulation, 4:76, 4:77*f*
 mitochondrial-type ferredoxins, 2:297
 multidrug resistance (MDR) membrane proteins, 3:214
 nickel-iron (NiFe) hydrogenases, 4:72–73
 nicotinamide adenine dinucleotide transhydrogenase, 3:247, 3:248*f*, 3:250, 3:250*f*
 non-homologous end joining (NHEJ), 3:266
 nucleoid-associated proteins (NAPs)
 characteristics and functional role, 3:367, 3:368*f*, 3:368*t*
 DNA supercoiling, 3:368–369, 3:369*f*
 gene expression regulation, 3:367–368
 topoisomerases, 3:369–370
 phage display, 3:431–436
 display vectors
 basic concepts, 3:431–432
 phagemid vectors, 3:432, 3:432*f*
 phage vectors, 3:432, 3:432*f*
 polyvalent/monovalent displays, 3:431–432
 phage-binding analysis, 3:435, 3:435*f*
 phage-binding selections
 affinity-based selection, 3:433–435, 3:435*f*
 binding and elution, 3:433–435
 preparation methods, 3:433
 phage libraries
 characteristics, 3:432–433
 diversity library design, 3:433, 3:434*t*
 sequence generation, 3:432–433, 3:433*t*, 3:434*t*
 research applications, 3:431
 phosphotransferase system (PTS), 2:387, 2:388*f*
 protein N-myristoylation, 3:642
 pterin distribution, 3:666
 pyruvate dehydrogenases (PDHs), 1:206–207, 4:326
 pyruvate kinase (PK), 3:719, 3:720*f*
 recombination-dependent DNA replication (RDR), 4:24
 RecQ helicases, 4:43–44, 4:44*f*
 reductive reactions, 1:487*t*
 Rep helicases
 characteristics and functional role, 3:261
 DNA unwinding
 active, rolling or hand-over-hand model, 3:264–265, 3:265*f*
 active versus passive mechanisms, 3:264
 dimeric inch-worm models, 3:265, 3:265*f*
 inch-worm mechanisms, 3:264, 3:264*f*, 3:265*f*
 protein oligomerization, 3:263
 unwinding mechanisms, 3:263–264
 research summary, 3:265
 single-strand DNA (ssDNA)
 translocation, 3:263, 3:264, 3:264*f*
 structural characteristics
 crystal structures, 3:262, 3:262*f*
 domain structures, 3:263*f*
 open and closed confirmations, 3:262–263
 primary structures, 3:261–262
 translocase-based protein displacement, 3:265
 respiratory chain complex I (NADH: ubiquinone oxidoreductase), 4:87–91
 basic concepts, 4:87, 4:341
 disease connections
 general discussion, 4:90–91

 characteristics, 3:544
- factor for inversion stimulation (Fis), 2:122,
 2:122f
- familial benign hypocalciuric hypercalcemia
 (FBHH), 1:326
- familial British dementia, 1:101t
- familial glucocorticoid deficiency (FGD),
 3:25–26
- familial hypocalciuric hypercalcemia (FHH),
 1:326, 1:329f
- familial partial lipodystrophy, 2:632t

- familial tumoral calcinosis, 2:471*t*
 Farber syndrome, 4:291*t*
 farnesoid X-receptor (FXR)-dependent
 mechanisms, 1:167, 1:169*f*
 farnesyl diphosphate, 1:516, 1:517*f*
 farnesyl isoprenoid, 4:244*f*
 farnesyl transferase, 2:737–738, 2:737*f*
 farnesyl transferase inhibitors (FTIs), 2:740
 Fas-associated protein with death domain
 (FADD), 1:389, 1:390*f*, 1:394*f*,
 1:617–619, 1:618*f*
 fasciculation and elongation protein zeta-1
 (FEZ1), 1:197*f*, 1:199, 1:200*f*
 Fascin, 1:29*f*, 1:34, 3:243, 3:244*f*
 Fat10 (diubiquitin), 4:468*t*, 4:471–472
 fatty acid 2-hydroxylase (FA2H) gene, 4:272
 fatty acids
 acyl-coenzyme A transesterification,
 1:384–385, 1:385*f*, 2:290, 2:291*f*
 anaplerotic pathways, 1:106*f*
 biosynthesis, 2:285–289
 de novo fatty acid biosynthesis,
 2:285–286
 lipogenic gene expression
 carbohydrate induction, 2:286–287
 highly unsaturated fatty acids
 (HUFAs), 2:287*f*, 2:288
 HUFA-response region with
 carbohydrate response element
 (CHORE), 2:288
 HUFA-response region with insulin
 response element (HUFA-RR/IRE),
 2:287–288
 nutritional regulation, 2:287–288
 omega-6/omega-3 fatty acids, 2:288
 saturated fatty acids
 basic concepts, 2:285–286
 energy metabolism regulation, 2:286
 malonyl-CoA, 2:285–286
 pyruvate dehydrogenase regulation,
 2:285–286
 unsaturated fatty acids
 arachidonic and docosahexenoic acid
 synthesis, 2:288, 2:288*f*
 oleic and palmitoleic acids, 2:288
 branched-chain amino acid (BCAA)
 regulation, 1:245–246
 carbohydrate-responsive element binding
 protein (ChREBP), 1:376, 1:376*f*
 cardiac metabolism, 3:66–67, 3:66*f*
 coenzyme A (CoA)
 peroxisome proliferator-activated
 receptor alpha (PPAR α),
 3:419–421, 3:420*f*
 4'-phosphopantetheine (4'-PP), 1:539
 synthesis process, 1:541
 fatty-acid binding proteins (FABPs), 2:281
 fatty acid metabolism
 AMP-activated protein kinase (AMPK),
 2:286, 4:56
 fatty acid synthase expression
 cancer diagnostics, 2:277–278
 functional role, 2:276–279
 human cancer expression, 2:277,
 2:277*f*
 inhibition mechanisms, 2:278–279

advanced glycation end products (AGEs)
AGE inhibitors and breakers, 2:409
AGE receptors, 2:407–409
aging effects, 2:409, 2:410f
alternative pathways, 2:407, 2:409f
basic concepts, 2:405
characteristics, 2:407, 2:408f
diabetes, 1:655–656, 2:409–410, 2:410f
disease effects, 2:410
RAGE (receptor for advanced glycation
end products), 2:407–409
alternative pathways, 2:407, 2:409f
basic concepts, 2:405, 2:406f
blood proteins
amino acids, 2:406
extracellular proteins, 2:406
glucose reactivity, 2:406–407
glycated hemoglobin
characteristics, 2:405
functional role, 2:405–406
plasma proteins, 2:406
glycooxidation, 2:407
Maillard reaction, 2:407
glyceraldehyde 3-phosphate (G-3-P)
gluconeogenesis, 2:382f, 2:384
glyceraldehyde-3-phosphate
dehydrogenase (G3PDH)
glycolytic pathway, 2:445f
metabolic regulation, 3:499–500
metabolite channeling, 3:80
myocardial ischemia, 3:67, 3:108–109
glycolysis
anaerobic glycolysis, 2:445f
glycolytic pathway, 2:443–444, 2:445f
pentose phosphate pathway, 3:391, 3:392,
3:393f, 3:394f
photosynthetic carbon dioxide (CO₂)
fixation
carbon pathway, 3:497, 3:499f
metabolic regulation, 3:499–500
regeneration phase, 3:499
thiamine diphosphate (ThDP), 1:207f
glycerate-3-phosphate (C3), 3:494f, 3:495f
glycerate-3-phosphate-kinase, 3:499f
glycerol
fermentation reactions, 2:204–206
glycerol-3-phosphate acyltransferase
(GPAT), 2:415
glycerol-3-phosphate dehydrogenase,
1:319t, 4:85
glycerol dehydratase, 1:156, 1:158t
glycerol phosphate dehydrogenase
(GPDH), 3:80, 4:19f, 4:20
lipolysis regulation, 1:50f
glycerolipids, 2:412–418
background information, 2:412
functional role, 2:414–415

glycerolipid receptors

intracellular receptors, 2:764
plasma membrane receptors, 2:762–764
phosphatidylcholine (PtdCho), 2:412,
2:413f, 2:414–415, 2:416f, 2:417f
phosphatidylethanolamine (PtdEtn),
2:412, 2:413f, 2:414–415, 2:416f
phosphatidylglycerol (PtdGro), 2:412,
2:413f, 2:414–415, 2:416f
phosphatidylinositol (PtdIns)
biosynthetic pathways, 2:416f
functional role, 2:414–415
phosphatidylinositol-3,4,5-triphosphate
(PIP₃), 3:447–451
binding proteins, 3:450
biosynthetic pathways, 3:449–450
cellular targets, 3:449f, 3:450–451
characteristics, 3:447
exosomes and microvesicles (EMVs),
2:262
phagocytosis regulation, 3:439–440
phosphatase and tensin (PTEN)
homolog, 1:563–564, 2:237f,
2:581f, 3:195–196, 3:439–440,
3:448f, 3:450
phosphatases, 3:450
SHIP1/SHIP2 phosphatases,
2:236–237, 3:439–440, 3:448f,
3:450
phosphatidylinositol-4,5-bisphosphate
(PIP₂), 3:447–451
actin depolymerizing factor (ADF)/
cofilin (ADF-H) domain, 1:22,
1:22f
affinity and sensitivity, 2:747
analytical methodologies, 2:746t
biosynthetic pathways, 3:447–448
cellular targets, 3:449, 3:449f
characteristics, 3:447
chemoattractant signaling,
2:236–238, 2:237f
cyclic adenosine monophosphate
(cAMP) receptors (cARs),
1:563–564
exosomes and microvesicles (EMVs),
2:262
functional role, 2:745–746, 2:748
glycogen synthase kinase-3 (GSK3),
2:435f
G protein-coupled receptor kinases
(GRKs), 2:485t
G-protein-coupled receptors (GPCRs),
4:225f
G_q family proteins, 2:497–498,
2:498f
hydrolysis mechanisms, 3:448–449
insulin signal transduction, 2:604,
2:604f
intracellular regulation overlap, 2:747,
2:747f
ion channel activity, 2:746–747,
2:746f, 2:746t
ion channel modulation, 2:746–747,
2:748
metabolic pathways, 3:448f
molecular structure, 3:448f, 3:460f

phospholipase C (PLC), 3:467–468,
3:468f
phospholipase D (PLD), 3:474–475,
3:474f
plectin, 2:625–627
regulation specificity, 2:747–748
research summary, 2:748
serotonin receptors, 4:225f, 4:226
transport modulation, 2:746–747
type I PIP kinases, 3:460–461, 3:460f
type II PIP kinases, 3:460f, 3:461
voltage-sensitive phosphatases, 2:746f
structural characteristics, 2:412, 2:413f
phosphatidylserine (PtdSer), 2:412,
2:413f, 2:414–415, 2:416f
phospholipid remodeling, 2:417f, 2:418
structural characteristics
diacylglycerol (DAG), 2:412–414, 2:414f
ether linked glycerolipids, 2:413, 2:414f
general discussion, 2:412–414
general structural features, 2:413f
sn-glycerol-3-phosphate, 2:412–414,
2:413f
lyso-phospholipids, 2:413–414, 2:415f
phosphatidic acid (PtdOH), 2:412–414,
2:413f
triacylglycerol (TAG), 2:412–414, 2:414f
synthesis process
anionic glycerophospholipids,
2:415–416, 2:416f
bioenergetics, 2:415
ether lipids, 2:417–418
neutral zwitterionic glycerolipids,
2:416–417, 2:416f
phosphatidic acid synthesis, 2:415,
2:416f
uncharged glycerolipids, 2:416–417,
2:416f
glyceroneogenesis, 1:105
glycerophospholipids, 2:733, 2:734f
glycinamide ribonucleotide (GAR)
transformylase, 2:325, 2:325f
glycine
arginine-glycine-aspartic acid (RGD)
peptide, 1:437–438, 1:439f, 2:608
classifications, 1:91, 1:92t
collagens
signature (Gly-X-Y)_n sequence
basic concepts, 1:545
evolutionary origins, 1:548
schematic diagram, 1:546f, 1:547f
self-assembly control, 1:546
cytochrome *c*, 1:600–601
elastin, 2:192
glycine decarboxylase, 1:142–143
glycine-phenylalanine-hydroxyproline-
glycine-glutamic acid-arginine
(GFOGER) sequence, 1:427t, 1:428
glycine receptors (GlyRs), 2:419–424
allosteric modulation
alcohol, 2:423
anesthetics, 2:423
background information, 2:423–424
cannabinoids, 2:423
glutamate, 2:423
ivermectin, 2:423

- neurosteroids, 2:423
- posttranslational modifications, 2:422*f*, 2:423–424
- zinc (Zn), 2:422*f*, 2:423

 lectins, 2:704–705

- N-linked glycosylation
 calcium-sensing receptor (CaSR), 1:327
 endoplasmic reticulum (ER)
 congenital disorders, 2:470, 2:471*t*
 glycosylation processes, 2:457, 2:458*f*
 protein synthesis and folding,
 4:204–205, 4:205*f*
 Golgi apparatus, 2:449–450, 2:449*f*,
 2:450*f*, 2:480, 4:207
 mammalian glucose transport,
 2:392–393
 mucins, 3:201
 plant glycoproteins, 2:465, 2:466*f*
 stromal interacting molecule 1 (STIM1),
 1:130*f*
 O-linked glycosylation, 2:465, 2:466*f*,
 2:480, 3:200–201, 4:207
 sugar chain–protein linkages, 2:469,
 2:470*t*
 sugar nucleotide transporters, 4:351
 glycosyl phosphatidylinositol (GPI)
 flippase proteins
 bacterial cell wall complex, 2:316–317
 biosynthesis, 2:316–317
 flippase-mediated transbilayer
 movement, 2:314, 2:315*f*
 glucosylceramide (Glc-Cer), 2:316,
 2:316*t*
 glycoprotein folding processes, 2:448–449
 glycosylphosphatidyl inositol (GPI)
 anchors, 2:737*f*, 2:737*t*, 2:738, 3:91*t*,
 3:92*f*, 3:93
 lipid rafts, 2:741, 2:742*f*, 2:743
 plant glycoproteins, 2:467, 2:467*f*
 glycosylphosphatidylinositol (GPI)-
 anchored proteins, 2:476–478
 biosynthesis
 attachment mechanisms, 2:476–477
 biosynthetic pathways, 2:476, 2:477*f*
 characteristics, 2:476
 functional roles, 2:478
 mammalian cells, 2:477–478
 parasitic protozoa, 2:477–478
 structural characteristics, 2:476, 2:477*f*
 yeasts, 2:477–478
 glycosyl transferases, 2:459*f*, 2:466, 3:231,
 4:207
 glyoxysomes, 3:425
 GM1 gangliosidosis, 4:291, 4:291*t*
 go-ichi-ni-san (GINS) proteins, 1:401–402,
 1:402*t*, 1:404*f*
 goldfish, 1:552*f*
 Golgi apparatus, 2:479–481
 actin-related proteins (Arps), 1:38*t*
 basic concepts, 2:479
 cholesterol biosynthetic pathway,
 1:517–519, 1:518*f*
 congenital disorders of glycosylation
 (CDG), 2:470–473, 2:471*t*
 flippase-mediated transbilayer movement,
 2:314, 2:315*f*, 2:316*t*
 glucosylceramide (Glc-Cer), 2:316, 2:316*t*
 Golgi α -mannosidase I, 3:258, 3:258*f*,
 3:259*t*
 Golgi α -mannosidase II, 3:258*f*, 3:259,
 3:259*t*, 4:504*f*
 intracellular calcium ion (Ca²⁺) stores,
 2:482, 2:574
 kinesin superfamily proteins (KIFs), 2:684*f*
 lipogenic gene expression, 2:286–287
 morphology
 cell polarity, 2:480
 cisternae, 2:479–480, 2:480*f*
 golgin proteins, 2:479
 microtubule organization, 2:480
 stacked morphology, 2:479, 2:480*f*
 subcellular localization, 2:479–480,
 2:480*f*
 N-linked glycoproteins
 flippase-mediated transbilayer
 movement, 2:314, 2:315*f*
 glycosidase digestion, 2:457–458,
 2:459*f*
 N-linked glycosylation, 2:449–450,
 2:449*f*, 2:450*f*, 2:480
 process mechanisms, 3:257
 structural remodeling, 2:457, 2:459*f*,
 2:460*f*, 2:461*f*
 O-linked glycosylation, 2:466, 2:480,
 4:207
 phosphatidic acid (PA), 3:476
 phosphatidylinositol 4-kinase (PI4K)
 pathway, 3:459–460
 protein processing
 protein glycosylation, 2:480
 proteolytic processing
 Alzheimer's disease, 2:481
 general discussion, 2:480–481
 prohormone processing, 2:480–481
 sterol regulatory element binding
 protein (SREBP), 2:481
 transcription factor regulation, 2:481
 proteoglycans, 3:659–660, 3:659*f*
 research summary, 2:482
 secretory pathway, 4:203–209
 compartmental organization, 4:203,
 4:204*f*
 microtubule-based motor proteins,
 4:208, 4:208*f*
 targeted proteins
 characteristics, 4:203
 constitutive secretion, 4:208
 entry mechanisms, 4:203, 4:205*f*
 integral membrane proteins, 4:204,
 4:205*f*
 protein exit, 4:207
 regulated secretion, 4:208
 signal recognition particles (SRPs),
 4:203, 4:205*f*
 soluble proteins, 4:204, 4:205*f*
 trans-Golgi network (TGN), 2:479–480,
 2:480*f*, 4:207, 4:208, 4:208*f*
 transport mechanisms
 protein localization, 4:206–207,
 4:206*f*
 protein modification, 4:207
 protein transport, 4:206*f*, 4:207
 resident enzyme localization, 4:207
 retinoid X receptor (RXR), 4:207
 vesicular transport, 4:206, 4:206*f*
 sugar nucleotide transporters, 4:350–351
 genetic mutations, 4:350
 macromolecular glycosylation
 regulation, 4:351
 structural characteristics, 4:350–351
 topographic characteristics, 4:351
 transport mechanisms, 4:350, 4:351*f*
 transport mechanisms
 cisternal progression, 2:481
 protein sorting
 basic concepts, 2:481–482
 KDEL receptor, 2:482
 mannose-6-phosphate receptor, 2:482
 protein aggregation, 2:482
 receptor-mediated sorting, 2:481–482
 vesicular transport, 2:481
 vacuole transport pathways, 4:503–506,
 4:505*f*
 gonadotropin-releasing hormone (GnRH)
 G_q family proteins, 2:496–497, 2:497*t*
 peptide amidation, 3:396
 gout, 2:312
 G-protein-coupled receptors (GPCRs)
 adrenergic receptors, 1:57–60
 action mechanisms, 1:57–58
 characteristics and functional role, 1:57
 classifications
 alpha-1 adrenergic receptors, 1:58,
 1:58*f*
 alpha-2 adrenergic receptors, 1:58,
 1:58*f*
 beta adrenergic receptors, 1:58*f*, 1:59
 characteristics, 1:57–58
 epinephrine
 branched-chain amino acid (BCAA)
 regulation, 1:245–246
 characteristics and functional role,
 1:57
 starvation effects, 4:303–304
 norepinephrine
 ascorbic acid, 4:531–532
 characteristics and functional role,
 1:57
 polymorphisms, 1:60
 regulation mechanisms, 1:59
 signal transduction pathways, 1:59
 allosteric proteins, 1:74
 anandamide synthesis, 2:194
 angiotensin, 1:112*t*, 2:344*t*, 2:345*f*
 arrestins, 1:496*f*
 blood-clotting proteases, 3:586*f*, 3:587
 bradykinin, 2:344*t*
 calcitonin receptor-like receptor (CLR),
 1:266, 1:267*f*
 calcitonin receptors (CTRs)
 distribution, 1:272
 isoforms, 1:272
 protein structure, 1:272, 1:272*f*
 regulatory mechanisms, 1:272
 signaling pathways, 1:272
 calcium/calmodulin-dependent protein
 kinase II (CaMKII), 1:297–298, 1:298*f*
 calcium-sensing receptor (CaSR),
 1:326–330
 biochemical characteristics
 agonists, 1:328
 amino acids, 1:327
 cell surface dimers, 1:327

G-protein-coupled receptors (GPCRs)

- heme proteins (*Continued*)
 sickle cell hemoglobin (HbS),
 2:534–535
 structural characteristics, 2:533
 myoglobin (Mb)
 allosteric regulation, 1:71
 carbon monoxide (CO), 2:534
 cyanide, 2:534
 functional role, 2:532
 oxygen-binding characteristics, 2:533,
 2:534f
 structural characteristics, 2:532, 2:533f
PET genes, 3:309
 photosynthetic reaction centers, 3:701f
 photosystem II (PSII) complex, 3:513f,
 3:514
 porphyric disorders, 2:542, 2:542t
 proton pumping, 3:664–665
 regulation mechanisms
 δ -aminolevulinic acid (ALA) function,
 3:547
 non-ALAS enzymatic regulation, 3:547
 structural characteristics, 2:532, 2:533f,
 2:539, 2:540f
 hemicellulose, 4:75f
 hemidesmosomes, 1:636–643
 assembly and maintenance, 1:642
 disease connections, 1:641t
 functional role
 cell–substrate adhesive function, 1:642
 general discussion, 1:643
 morphogenetic functions, 1:642
 transmembrane signaling function,
 1:642–643
 wound healing, 1:642–643
 integrin–extracellular matrix (ECM)
 contacts, 1:439f, 2:611f
 molecular components
 $\alpha\beta 4$ integrin heterodimer, 1:640f,
 1:641, 1:641t, 1:642–643
 BPAG1 protein, 1:641, 1:641t
 CD151, 1:642
 laminin-332, 1:641t, 1:642
 plectin, 1:641–642, 1:641t
 structural characteristics, 1:640–642,
 1:640f
 type XVII collagen, 1:640f, 1:641,
 1:641t
 ultrastructure, 1:640, 1:640f
 hemoglobin (Hb)
 carbon monoxide (CO), 2:534
 cyanide, 2:534
 glycated hemoglobin
 characteristics, 2:405
 functional role, 2:405–406
 hemoglobin mutants
 blood substitutes, 2:535
 fetal hemoglobin (HbF), 2:534
 sickle cell hemoglobin (HbS),
 2:534–535
 methemoglobin formation, 2:534
 nicotinamide adenine dinucleotide
 (NAD⁺/NADH) fluorescence, 4:277
 oxygen-binding characteristics
 allosteric regulation, 2:534, 2:534f
 Bohr effect, 2:534
 2,3-diphosphoglycerate (2,3-DPG),
 2:534
 oxygen–hemoglobin (O₂–Hb) binding,
 1:71, 1:72f
 spectrophotometric assays, 4:277
 structural characteristics, 2:533
 hemokinin 1
 functional role, 4:361
 synthesis, 4:361f
 Henri's equation, 2:216–218
 heparan sulfate (HS)/heparin, 3:655–656,
 3:655f, 4:511
 heparan sulfate proteoglycans (HSPGs),
 1:439–440, 2:303–304, 4:511
 heparin pentasaccharide, 1:2f
 hepatic carcinoma, 1:192f, 1:193–195
 hepatic gluconeogenesis, 2:384, 4:305–306,
 4:306f
 hepatic insulin resistance, 1:650, 1:650f
 hepatic mitochondria, 2:375–376, 2:375f
 hepatitis
 anti-mitochondrial antibodies (AMAs),
 3:116
 hepatitis B virus (HBV), 3:12–13, 3:13f,
 3:303t
 hepatitis C virus (HCV), 4:156–157
 hepatitis delta virus (HDV), 4:156–157
 hepatitis delta virus (HDV) ribozyme,
 4:144, 4:146f
 nuclear factor kappa B (NF- κ B), 3:303t,
 3:304–305
 primary biliary cirrhosis (PBC), 3:562
 hepatocytes
 healthy adult liver, 1:190–191, 1:191f
 intracellular calcium ion (Ca²⁺) waves,
 2:644
 liver regeneration, 1:192f, 1:193–195,
 1:194f
 peroxisome proliferator-activated receptor
 alpha (PPAR α), 3:420
 heptasaccharide intermediate
 (Man₅GlcNAc₂-P-P-Dol), 2:315–316,
 2:315f, 2:316t
 HER2/*neu* gene, 2:278
 herbicides, 3:547
 Herc5, 4:468t, 4:471
 hereditary inclusion body myopathy type II,
 2:471t, 2:475
 hereditary nonpolyposis colorectal cancer
 (HNPCC), 2:61–64, 2:62t, 2:63f
 hereditary spastic paraplegias (HSPs),
 4:267–272
 axonal degeneration, 4:267
 definition, 4:267
 endosomal localization
 cytochrome P-450 (CYP), 4:271
 developmental genes, 4:272
 lipid metabolism, 4:270–271
 maspardin/SPG21, 4:269f, 4:270–272
 mitochondrial proteins
 Hsp60 protein/SPG13, 4:271–272
 paraplegin/SPG7, 4:271
 myelin–axonal interactions, 4:272
 neuropathy target esterase (NTE), 4:271
 seipin, 4:269f, 4:270–271
 genetic bases, 4:267, 4:268t
 neuropathology, 4:267
 pathogenesis
 cellular trafficking genes
 atlastin-1/SPG3A, 4:269, 4:269f
 KIF5A/SPG10, 4:269f, 4:270
 NIPA1/SPG6, 4:269f, 4:270
 receptor-enhancing protein 1
 (REEP1)/SPG31, 4:269f, 4:270
 spartin/SPG20, 4:269f, 4:270
 spastin/SPG4, 4:268–269, 4:269f
 motor neurons, 4:267–270, 4:269f
 Herlitz junctional epidermolysis bullosa
 (JEB), 1:641t
 Hermansky–Pudlack syndrome, 4:507–508,
 4:507t
 herpes simplex virus (HSV), 4:240, 4:240f,
 4:459
 herpesvirus entry mediator (HVEM), 4:454,
 4:455, 4:456f, 4:457f
 Hers disease, 2:427t, 2:431t, 2:432
 heterochromatin, 1:521, 3:296–297, 3:297f,
 3:314–315, 3:315f
 heterocyclic amino acids, 1:92t
 heteropentamers, 2:347, 2:348f
 heterotrimeric G proteins
 carboxyl methylation, 3:608–609, 3:608f
 phagocytosis, 3:439
 heterotrophic glutathione reductase (GR)-
 type FNRs, 2:301
 [Het-s] prion
 disease states, 3:568–569
 genetic properties, 3:566
 prion domains, 3:568f
 self-propagating amyloidoses, 3:567–568
 hexanoate
 branched-chain amino acid (BCAA)
 regulation, 1:245–246
 medium-chain acyl-CoA synthetase
 (MCAS), 2:292
 hexokinase, 2:543–547
 catalytic reaction mechanisms, 2:543
 classifications, 2:544
 evolutionary development, 2:544, 2:545f
 hexokinase IV
 insulin-secreting cells (β -cells), 2:547
 liver glucokinase/glucokinase regulatory
 protein (GCKR), 2:547
 sigmoidal kinetics, 2:546–547, 2:546f
 ischemic-induced metabolic signaling
 alterations, 3:68, 3:69f
 isozymic diversity, 2:543–544, 2:544t
 mammalian low-*K_m* hexokinases
 activity regulation, 2:546
 glucose-6-phosphate (glucose-6-P)
 inhibition, 2:546
 subcellular localization, 2:546
 structural characteristics, 2:544–546,
 2:545f
 sugar phosphorylation, 2:543
 hexosamine biosynthetic pathway, 1:656,
 3:351f
 hexosaminidases A and B, 4:292
 HExxH motif, 4:50–53
 HhaI enzyme, 2:131, 2:132t
 Hhat proteins, 2:736–737
 high-density lipoproteins (HDLs)

- adiponectin, 3:74
 vitamin E, 4:548
 highly unsaturated fatty acids (HUFAs)
 HUFA-response region with carbohydrate response element (CHORE), 2:288
 HUFA-response region with insulin response element (HUFA-RR/IRE), 2:287–288
 lipogenic gene expression, 2:287f, 2:288
 high-mannose-bearing mannose-6-phosphate residues, 2:461f, 2:463–464
 high-mobility group (HMG) proteins, 1:314–315
 high-performance liquid chromatography (HPLC), 2:590–591
 high-voltage-activated channels (HVA), 4:561t
 HinfIII enzyme, 2:136, 2:137t
 Hin invertase, 1:560–561
 hippocampus, 1:196–197, 1:197f, 2:172t
 hippurate, 4:495f
 hisactophilin, 3:438–439
 histamines, 2:496–497, 2:497t
 histidine
 acyl-coenzyme A synthetase, 2:291f
 anaplerotic pathways, 1:106f
 classifications, 1:92t
 cysteine protease action mechanisms, 1:589, 1:590f
 cytochrome *c*, 1:600–601
 glycation processes, 2:406
 histidine kinases, 1:629, 1:630f
 histidine protein (HPr), 2:387, 2:388f
 low barrier hydrogen bonds (LBHBs), 2:758–759, 2:758f
 metalloproteases, 3:87, 3:87f, 4:50–53
 phage libraries, 3:434t
 proline-histidine-serine-arginine-asparagine (PHSRN) sequence, 1:426
 tricarboxylic acid cycle, 4:439f
 zinc-finger domains, 4:573–574, 4:573f, 4:575, 4:576f
 histone-like nucleoid-structuring protein (H-NS), 3:367, 3:368f, 3:368t
 histones
 centromeric histone CENP-A, 1:448–450, 1:449f, 1:538
 core histones
 chromatin structure, 1:535–537
 gene variants
 characteristics, 1:531–532
 histone H1, 1:531
 nonhistone chromatin proteins (NHCPs), 1:531–532
 post-translational modifications, 1:530–531
 de novo DNA methylation, 3:6–8, 3:7f
 gene expression regulation, 1:314–315
 histone acetyltransferase (HAT), 1:311, 1:521, 1:530–531, 2:110, 4:541f, 4:543–544
 histone acetyltransferases (HATs), 4:60
 histone deacetylases (HDACs), 1:181, 1:181f, 1:312, 1:406–407, 1:407f, 1:521, 1:530–531, 2:110, 4:60
 histone H3 lysine 4 (H3K4)/histone H3 lysine 9 (H3K9) methylation, 3:6–8, 3:7f
 histone locus bodies, 3:300–301
 nucleosome regulation
 acetylation, 1:521, 1:522f, 4:60
 citullination, 4:62
 covalent modifications, 1:521, 1:522f, 4:59
 histone variants, 4:60f, 4:62–63
 methylation, 1:521, 1:522f, 4:60–61
 phosphorylation, 1:314–315, 1:521, 1:522f, 4:61
 proteolysis, 4:62
 sumoylation, 4:62
 ubiquitylation, 4:61–62
 nucleosome structure, 1:535–537, 1:536f
hixL/hixR recombination sites, 1:558
 HK022 Nun protein, 4:410–411
 HMGN1 protein, 4:404
 hnRNP protein family, 1:76–77, 1:78f, 1:79–80, 1:79f
 Hodgkin's disease, 4:161
 Holliday junctions (HJs), 1:449–450, 2:242–243, 2:558, 2:559f, 4:29, 4:30f, 4:33

kinases (*Continued*)

G-protein-signaling regulators (RGSs), 2:493

G_q family proteins, 2:497–498, 2:498f

hematopoietin receptors, 2:528f

hemidesmosome function, 1:642–643

hydrogen peroxide (H₂O₂), 3:173

insulin-like growth factor-1 (IGF1), 1:198–199, 1:200f

insulin receptors (IRs), 2:602–603

insulin resistance mechanisms, 1:651, 1:651f

insulin signal regulation, 2:606

insulin signal transduction, 2:605–606

c-jun N terminal kinase (JNK) pathway

angiotensin receptors, 1:113

c-fes proto-oncogene (Fes), 1:453

functional role, 3:177–178

glycogen synthase kinase-3 (GSK3), 2:435f, 2:436t

hydrogen peroxide (H₂O₂), 3:173, 3:173f

insulin resistance, 2:606–607

insulin signal transduction, 2:605–606

integrin signaling, 2:611

mitochondrion-dependent apoptosis, 3:174

muscarinic acetylcholine receptors, 3:216

neurogenesis, 1:199

nitric oxide (NO), 3:173, 3:173f

p75 neurotrophin receptor (p75NTR), 3:245, 3:245f

phylogenetic relationships, 3:177f

signaling cascades, 3:177f

toll-like receptors (TLRs), 4:398–399

mTOR complexes, 1:408, 3:195–196

multiple opioid receptors, 3:357

muscarinic acetylcholine receptors, 3:216

neurogenesis, 1:198–199, 1:200f

neurokinin-1 receptor (NK1R), 4:362–363

neurotrophins, 3:241–243, 3:242f

nitric oxide (NO), 3:173

nuclear signal transmission specificity and fidelity, 3:178–179

p38 kinase

angiotensin receptors, 1:113

chemokine receptors, 1:480–482

functional role, 3:178

G protein-coupled receptor kinases (GRKs), 2:485t

G-protein-signaling regulators (RGSs), 2:493

muscarinic acetylcholine receptors, 3:216

neurokinin-1 receptor (NK1R), 4:362–363

phylogenetic relationships, 3:177f

signaling pathways, 1:618f, 1:620f, 3:177f

pheromone receptors, 3:441–442, 3:443f

phylogenetic relationships, 3:177f

platelet-activating factor receptor (PAFR), 3:536, 3:536f

platelet-derived growth factor (PDGF) receptors, 3:541f

RAGE (receptor for advanced glycation end products), 2:407–409

somatostatin (sst) receptors, 4:265

steroid/thyroid hormone receptors, 4:310f

T-cell receptors (TCRs), 4:374

toll-like receptors (TLRs), 4:398–399

vascular endothelial growth factor receptors (VEGFRs), 4:512

myosin light chain kinase (MLCK)

calcium ion (Ca²⁺)–calmodulin (CaM)-dependent protein kinases (CaMKs), 1:305–306, 1:305f

cell migration, 1:440–441, 1:441f

EF-hand proteins, 1:319t, 1:321

focal adhesions, 2:322, 2:322f

G₁₂/G₁₃ family functions, 2:345f

somatostatin (sst) receptors, 4:265

nuclear factor kappa B (NF-κB)-inducing kinase (NIK), 4:456, 4:458f

p21-associated kinase (PAK), 1:440–441, 1:441f, 2:611, 3:441–442, 4:113

p38 kinase

angiotensin receptors, 1:113

chemokine receptors, 1:480–482

functional role, 3:178

G protein-coupled receptor kinases (GRKs), 2:485t

G-protein-signaling regulators (RGSs), 2:493

muscarinic acetylcholine receptors, 3:216

neurokinin-1 receptor (NK1R), 4:362–363

phylogenetic relationships, 3:177f

signaling pathways, 1:618f, 1:620f, 3:177f

partitioning defective (PAR)/atypical protein-kinase (aPKC) complex, 1:262–263

PERK (PKR-like ER kinase), 2:524–525, 2:524f, 4:491

phosphatidylinositol 3-kinase (PI3K) pathway

angiotensin receptors, 1:113

B-cell antigen receptors (BCRs), 1:162–163, 1:163f

cellular functions, 3:461

c-fes proto-oncogene (Fes), 1:454

chemoattractant signaling, 2:236–238, 2:237f

cyclic adenosine monophosphate (cAMP) receptors (cARs), 1:563–564

diabetes treatments, 1:657

DNA damage checkpoints proteins, 1:411t

focal adhesion kinase (FAK) family, 2:265–266

G_{βγ} subunit functions, 1:480–482, 1:482f, 2:377, 4:265

glycogen synthase kinase-3 (GSK3), 2:435f

hematopoietin receptors, 2:526, 2:528f

hemidesmosome function, 1:642–643

insulin receptors (IRs), 1:198–199, 1:200f, 2:602–603

insulin resistance mechanisms, 1:651, 1:651f

insulin signal regulation, 2:606

insulin signal transduction, 2:604

integrin signaling, 2:611

liver regeneration, 1:193–195

macroautophagy regulation, 1:149

mTOR complexes, 1:408, 3:195–196, 3:197

neurokinin-1 receptor (NK1R), 4:362–363

neurotransmitter transporters, 3:239

neurotrophins, 3:241–243, 3:242f

phagocytosis regulation, 3:439–440

platelet-activating factor receptor (PAFR), 3:536, 3:536f

platelet-derived growth factor (PDGF) receptors

chemotaxis, 3:542

mediated cellular responses, 3:541, 3:541f

signaling pathways, 3:539–540, 3:540f

small guanosine phosphatases (GTPases), 4:247f, 4:248

sodium–potassium (Na⁺–K⁺)-ATPase pump, 3:687

somatostatin (sst) receptors, 4:265

transforming growth factor beta (TGF-β), 1:620f

vacuole transport pathways, 4:504–506

zinc-finger domains, 4:578

phosphatidylinositol-4,5-bisphosphate (PIP₂), 3:448f

phosphatidylinositol 4-kinase (PI4K) pathway

cellular functions, 3:459–460

subfamilies, 3:459

phosphatidylinositol phosphate kinases (PIP kinases)

domain structures, 3:460, 3:460f

type I PIP kinases, 3:460–461, 3:460f

type II PIP kinases, 3:460f, 3:461

type III PIP kinases, 3:460f, 3:461

phosphoinositide 3-kinase-like kinase (PIKK) family, 1:412–413, 1:413f

phosphoinositide-dependent protein kinases, 3:463–466

functional role, 3:463

kinase S6 kinase (S6K), 2:604f, 2:605, 3:464f, 3:465

mTOR (rapamycin), 3:464f, 3:465

phosphoinositide 3-kinase (PI 3-kinase)

lipid signaling pathway, 3:448f, 3:463, 3:464f

phosphoinositide-dependent kinase 1 (PDK1), 3:464–465, 3:464f, 4:377–378

phosphoinositide-dependent kinase 2 (PDK2), 3:464f, 3:465

- protein kinase B (PKB), 3:463–464
 research summary, 3:466
 tyrosine kinases (Tec family), 3:465–466
 phosphorylase kinase (PhK), 1:305f, 1:306
- protein kinase A (PKA)
 adipocyte development, 1:55
 arachidonic acid regulated Ca^{2+} (ARC)
 channels, 1:129
 binding specificity and affinity,
 1:577–578
 carbohydrate-responsive element
 binding protein (ChREBP),
 1:375–376, 1:376f
 characteristics and functional role,
 1:575–577
 cyclic adenosine monophosphate
 (cAMP) receptors (cARs),
 1:563–564, 1:564f
 feed-forward control, 1:578–579, 1:578f
 glycogen synthase kinase-3 (GSK3),
 2:435f
 G protein-coupled receptor kinases
 (GRKs), 2:485t
 insulin-secreting cells (β -cells), 2:597f
 liver PK (LPK) *in vitro* regulation, 3:719
 negative feedback, 1:578–579, 1:578f
 neurogenesis, 1:199
 Perilipin 1 (Plin1), 1:47–48, 1:48f
 phosphofructokinase-2/fructose
 biphosphatase-2 (PFK-2/FBPase-2)
 activation, 3:457–458
 PKA-mediated lipolysis, 1:49–51, 1:50f,
 4:303–304
 plasma membrane calcium (Ca^{+})-
 ATPase pump, 3:525–526
 structural domains, 1:574–575, 1:575f,
 1:576f
 substrate specificity, 1:578
- protein kinase B (PKB)
 cyclic adenosine monophosphate
 (cAMP) receptors (cARs),
 1:563–564, 1:564f
 functional role, 3:463–464
 glycogen synthase kinase-3 (GSK3),
 2:435f
 insulin signal transduction, 2:604
 mTOR complexes, 1:408, 3:195–196
 neurokinin-1 receptor (NK1R),
 4:362–363
 neurotransmitter transporters, 3:239
 phosphatidylinositol-3,4,5-
 trisphosphate (PtdIns-3,4,5- P_3),
 3:450
- protein kinase C (PKC), 3:637–640
 arachidonic acid regulated Ca^{2+} (ARC)
 channels, 1:129
 background information, 3:637
 bile salts, 1:169
 calcium ion (Ca^{2+}) signaling system,
 2:719–720, 2:720f
 calcium oscillation decoding, 1:325
 calcium-sensing receptor (CaSR), 1:328,
 2:583, 2:584f
 chemokine receptors, 1:480–482, 1:482f
 diabetes, 1:656
 domain structures, 3:637, 3:638f
 downregulation, 3:639
 $\text{G}_{12}/\text{G}_{13}$ family functions, 2:345f
 $\text{G}_{\beta\gamma}$ subunit functions, 1:480–482,
 1:482f, 4:265
 gene expression regulation, 1:311
 glycogen synthase kinase-3 (GSK3),
 2:435f
 G protein-coupled receptor kinases
 (GRKs), 2:485t
 G_q family proteins, 2:497–498, 2:498f
 historical research, 3:637
 insulin resistance, 1:650
 insulin-secreting cells (β -cells), 2:597f
 insulin signal transduction, 2:604
 isozyme families, 3:637, 3:638f
 mitochondrial permeability transition
 pore, 3:165–166
 neurogenesis, 1:199
 neurokinin-1 receptor (NK1R),
 4:362–363
 neurotransmitter transporters, 3:239
 neurotrophins, 3:241–243, 3:242f
 nuclear calcium signal, 1:310–311
 phospholipase D (PLD), 3:472–473,

 characteristics, 4:293
 chemokine receptors, 1:480–482, 1:482f
 focal adhesion kinase (FAK) family,
 2:265–266, 2:267f, 2:611,
 4:294–295
 focal adhesions, 2:321
 functional role, 4:294
 group III 5-phosphatases, 3:462
 guanine-nucleotide-exchange factors
 (GEFs), 4:245, 4:246f
 hematopoietin receptors, 2:526, 2:528f
 historical research, 4:293–294
 immune responses, 4:294–295
 invertebrate Src kinases, 4:297
 neurokinin-1 receptor (NK1R),
 4:362–363
 phosphorylation, 4:295–297, 4:296f
 platelet-derived growth factor (PDGF)
 receptors
 chemotaxis, 3:542
 mediated cellular responses, 3:540,
 3:541f
 signaling pathways, 3:539–540,
 3:540f
 protein palmitoylation, 2:738,
 4:296–297, 4:296f
 protein prenylation, 2:737t
 protein tyrosine kinase (PTK), 1:162,
 1:163f, 3:470
 redundant functions, 4:294
 regulation mechanisms, 4:295–297,
 4:296f
 research summary, 4:297
 SH2/SH3 domains, 1:451–452, 1:452f,
 4:294, 4:295–297, 4:296f
 signaling adhesion functions, 4:294–295
 steroid/thyroid hormone receptors,
 4:310f
- Stt1/STN8, 1:514, 1:514f
 stress-activated protein kinase (SAPK),
 3:177–178, 3:177f
 Stt7/STN7, 1:513, 1:513f, 1:514, 1:514f
 Syc family kinases, 2:611
 thylakoid protein kinase network, 1:514,
 1:514f
 tyrosine kinase receptors (Trks)
 glycogen synthase kinase-3 (GSK3),
 2:435f
 messenger RNA (mRNA), 2:602–603
 neurotrophins
 cross-talk, 3:246
 functional role, 3:241
 p75 neurotrophin receptor (p75NTR),
 3:246

kinases (*Continued*)

 open reading frames (ORFs), 3:60–61

- research summary, 3:64
 RNA-binding proteins, 3:59–60, 3:60f, 3:62–63
 spliceosomes, 3:62–63, 3:63f
 RNA trafficking, 3:323
 thiamine biosynthesis, 1:203–204
 3'-end maturation
 basic concepts, 3:59–60, 3:60f
 cleavage sites, 3:188–189
 gene expression regulation, 3:192
 polyadenylation, 3:188
 protein complexes, 3:189–191, 3:189f, 3:190t
 regulation mechanisms, 3:191–192
 untranslated regions (UTRs), 3:188, 3:192
 transcription and translation processes, 4:418
 translation initiation, 4:425–431
 basic concepts, 4:425
 eukaryotes
 AUG triplets, 4:433–435
 80S initiation complex, 4:434f
 80S ribosome formation, 4:435
 eukaryotic initiation factors (eIFs), 4:433t, 4:434f, 4:435
 5' leader scanning, 4:433
 40S ribosomal subunits, 4:432
 43S preinitiation complexes, 4:433, 4:434f
 48S initiation complex, 4:435
 initiation codon selection, 4:433–435
 initiation mechanisms, 4:432
 internal ribosomal entry sites (IRESs), 4:435
 regulation mechanisms, 4:435
 ribosomal dissociation, 4:432
 60S ribosomal subunits, 4:432, 4:435
 40S ribosomal subunits, 4:432
 initiation complex formation, 4:426–427
 initiation factors
 initiation factor 1 (IF1), 4:427–428, 4:427f, 4:428f
 initiation factor 2 (IF2), 4:427f, 4:428–430
 initiation factor 3 (IF3), 4:427f, 4:428f, 4:429f, 4:430
 structure and functions, 4:427–431
 ribosomal dissociation, 4:432
 70S initiation complex, 4:130f, 4:426–427, 4:427f
 60S ribosomal subunits, 4:432
 30S initiation complex, 4:130f, 4:132f, 4:426–427, 4:427f, 4:429f
 translation initiation region (TIR), 4:425–426, 4:426f
 uncoupling proteins (UCPs), 4:484–485, 4:485f
 metabolic syndrome (syndrome X), 1:654
 metabolite channeling, 3:80–85
 action mechanisms, 3:80
 advantages, 3:80–81, 3:81f
 basic concepts, 3:80
 creatine kinase/phosphocreatine circuit, 3:81, 3:82f
 cytosolic creatine kinase, 3:81–82, 3:82f
 energy-transducing mitochondrial microcompartments, 3:82–84, 3:83f
 glycolytic multienzyme complexes, 3:81
 mitochondrial CK (MtCK) isoenzyme energy-transducing microcompartments, 3:82–84, 3:83f
 intramitochondrial inclusions, 3:84, 3:84f
 low-cellular-energy state, 3:84
 microcompartments, 3:82–84
 mitochondrial permeability transition pore, 3:84
 subcellular microcompartments, 3:80
 metabotropic glutamate (mGlu) receptors, 2:395–398
 characteristics, 2:716t
 fast excitatory synaptic transmission, 2:395
 functional role, 2:396–397, 2:714–716, 2:715t
 gene families, 2:395–396, 2:396f
 molecular structure, 2:717f
 neuromodulation, 2:395
 protein structure, 2:717f, 2:719
 research background, 2:395
 schematic diagram, 2:396f
 therapeutic potential, 2:397
 metachromatic leukodystrophy, 4:291t
 metalloelastase, 3:91t, 3:92f, 3:93
 metalloproteases, 3:86–89
 AAA (ATPases associated with various cellular activities) proteins, 1:3–5, 1:3t, 1:4f, 1:6
 characteristics, 3:86
 FtsH metalloprotease, 1:3t, 1:4f, 1:6
 functional classification, 3:86
 genetic origin, 3:88
 inhibitors
 catalytic chelators, 3:88f, 3:89
 general discussion, 3:88–89
 metal-bound water displacement, 3:88f, 3:89
 metal hydroxide complexes, 3:88f, 3:89
 ligand nature, 3:88
 physiological functions, 3:88
 regulated intramembrane proteolysis (RIP), 4:50–53
 structural classification
 catalytic sites, 3:87, 3:87f
 cocatalytic sites, 3:87–88
 metal sites, 3:86–87, 3:87f, 4:50–53
 research background, 3:86–88
 structural sites, 3:87
Metallospira, 3:34
 metaphase I, 3:19f, 3:20
 metazoans
 alternative oxidases (AOXs), 1:145–146
 conventional actin, 1:38–40
 septins, 4:217f, 4:218
 S phase initiation proteins, 1:402t
 unfolded protein response (UPR)
 ATF6 gene activation, 4:490–491, 4:491f
 inositol requiring 1 (IRE1) gene conservation, 4:490
 intramembrane proteolysis, 4:490–491
 metformin, 1:657
Methanobacterium, 3:32–34
Methanobacterium formicicum, 4:89
Methanobacterium thermoautotrophicum
 Cho phylogenetic tree, 3:331f
 initiation factors, 4:428–430, 4:428f
 uvrC phylogenetic tree, 3:331f
Methanocaldococcus jannaschii, 2:564f, 2:566, 4:50
Methanococcus, 3:32–34
Methanococcus jannaschii, 2:72–73, 3:34
Methanococcus maripaludis, 1:457f
 methanogenesis
 anaerobic respiration, 2:207f
 archaeal energy transduction, 3:32–33, 3:33f
 bacterial reductive reactions, 1:487t
 cobalamin, 1:159–160
Methanobolus, 3:32–34
Methanopyrus kandleri, 2:157, 2:158t, 2:566
Methanosarcina, 3:32–34
Methanosarcina barkeri
 biosynthetic pathway, 3:546
 reductive reactions, 1:487t
 respiratory chain complex I (NADH: ubiquinone oxidoreductase), 4:88–89
Methanosarcina mazei, 4:89
Methanothermobacter, 4:146f
Methanothermobacter marburgensis, 1:125
Methanothermus, 3:32–34
Methanotrix, 3:32–34
 methemoglobin, 2:534
 methionine
 anaplerotic pathways, 1:106f
 carnitine, 1:384
 cobalamin-dependent methionine synthase, 1:159, 1:159f, 2:327
 cytochrome *c*, 1:600–601
 folate coenzymes, 2:324–326, 2:325f
 metalloproteases, 3:87–88
 methionine aminopeptidases (MetAPs)
 general discussion, 1:97–99
 isoform functions, 1:98–99
 metal use, 1:98
 structural organization, 1:98, 1:98f
 substrate specificity, 1:98
 methionine sulfoxide reductase, 3:411f
 methylenetetrahydrofolate reductase, 2:312–313
 mitochondrial DNA (mtDNA), 3:134t
 phage libraries, 3:434t
 methoxamine, 1:58
 methoxy-4-hydroxymandelic acid (VMA), 1:57
 methoxy-4-hydroxyphenylglycol (MHPG), 1:57
 methyladenine, 2:1, 2:2f
 methylation, 2:9, 4:60–61
 methyl binding domain IV (MBD4)
 cancer prevention, 4:78
 comparison diagram, 1:523f
 DNA demethylation, 3:9, 3:10f
 DNA glycosylases, 2:16
 functional role, 1:523–524
 mismatch repair (MMR), 1:523f
 specificity, 4:77–78
 structure and biochemistry, 4:77

- α -methylbutyryl-CoA, 1:244, 1:245f
 methyl-CpG-binding proteins, 1:521–524
 binding domain family
 general discussion, 1:522
 MBD1, 1:523, 1:523f
 MBD2, 1:523, 1:523f
 MBD3, 1:523, 1:523f
 MBD4
 cancer prevention, 4:78
 comparison diagram, 1:523f
 DNA demethylation, 3:9, 3:10f
 functional role, 1:523–524
 mismatch repair (MMR), 1:523f
 specificity, 4:77–78
 structure and biochemistry, 4:77
 MBD5, 1:523f, 1:524
 MBD6, 1:523f, 1:524
 MeCP2, 1:522–523, 1:523f
 cytosine methylation
 basic concepts, 1:522
 cancer cells, 1:522
 functional role, 1:522
 gene expression regulation, 1:522
 genomic imprinting, 1:522
 X-chromosome inactivation, 1:522
 DNA methylation–chromatin structure
 interdependency, 1:524
 functional role, 1:521
 gene expression regulation, 1:521
 glycosylation processes, 3:9, 3:10f
 β -methylcrotonoyl-coenzyme A (CoA)
 carboxylase, 1:221
 2-methyleneglutarate mutase, 1:158t
 methylenetetrahydrofolate reductase
 (MTHFR), 2:312–313, 2:325f, 2:326
 methylenetetrahydrofolate acid (THF),
 3:715–716, 3:715f
 methylesterase (MEase), 3:607, 3:609–610,
 3:609f
 O⁶-methylguanine-DNA methyltransferase
 (MGMT), 2:12–13
 methylmalonic acidemia, 4:495t
 methylmalonyl-CoA, 2:208, 2:208f
 methylmalonyl CoA mutase, 1:158t, 2:327
 methylmethanesulfonate (MMS), 2:9, 2:10f,
 4:48–49
 N-methyl-N'-nitro-N-nitrosoguanidine
 (MNNG), 2:9, 2:10f, 2:51–52, 2:52f
 N-methyl-N-nitrosourea (MNU), 2:9, 2:10f
 Methylococcus capsulatus, 1:489t, 3:331f
 Methylomirabilis oxyfera, 1:489t
 methyltransferase (MTase)
 carboxyl methylation, 3:607, 3:609–610
 cytosine methylation
 basic concepts, 1:522, 3:6, 3:7f
 cancer cells, 1:522
 functional role, 1:522
 gene expression regulation, 1:522
 genomic imprinting, 1:522
 X-chromosome inactivation, 1:522
 deoxyribonucleic acid (DNA), 2:40–44,
 3:6–10
 basic concepts, 3:6, 3:7f
 Dam methyltransferase
 altered gene expression, 2:42–43
 bacterial pathogenesis, 2:43
 chromosome replication, 2:42
 dam mutant strains, 2:40
 gene inactivation, 2:43–44
 mismatch repair, 2:40–42, 2:41f, 2:42f
 Mut protein system, 2:40–42, 2:41f,
 2:42f
 oriC region, 2:42
 post-transcriptional regulation, 2:43
 properties, 2:40
 viruses, 2:43–44
 DNA demethylation
 glycosylation processes, 3:9, 3:10f
 hydroxylation processes, 3:9
 Dnmt1, 3:8–9, 3:8f
 Dnmt3 family
 characteristics, 3:6, 3:7f
 CpG dinucleotide spacing, 3:6
 de novo DNA methylation, 3:6, 3:7f
 Dnmt3a, 3:6, 3:7f
 Dnmt3L, 3:6, 3:7f
 histone H3 lysine 4 (H3K4)/histone
 H3 lysine 9 (H3K9) methylation,
 3:6–8, 3:7f
 5-methylcytosine (5mC), 3:9, 3:9f
 research summary, 3:9–10
 SET- and RING-associated (SRA)
 domain, 3:9, 3:9f
 type II restriction and modification
 enzymes, 2:134
 type III restriction and modification
 enzymes, 2:137–138, 2:137t
 UHRF1 (ubiquitin-like, containing PHD
 and RING finger domains 1), 3:9,
 3:9f
 methylurapidil, 1:58
 metoprolol, 1:59
 mevalonic acid (MVA)
 brassinosteroid biosynthesis, 1:251
 3-hydroxy-3-methylglutaryl coenzyme A
 (HMG-CoA) reductase regulated
 degradation, 1:518f, 1:519
 Mevinolin, 1:519
 Mfd protein, 3:335–336, 3:335f, 4:409
 Mgm1, 4:51f, 4:54
 mice
 DNA mismatch repair (MMR), 2:52
 fatty acyl-coenzyme A (CoA) synthetases,
 2:294
 nicotinic acid adenine dinucleotide
 phosphate (NAADP)-induced calcium
 ion (Ca²⁺) release, 2:638t
 superoxide dismutases (SODs), 4:354
 Michaelis complex, 2:758–759, 2:758f
 Michaelis constant (V/K), 4:348–349
 Michaelis-Menten/Briggs-Haldane
 equations, 4:273–274, 4:274f
 Michaelis-Menten equation, 2:216–217
 microarrays
 DNA microarrays
 basic concepts, 2:370–371
 data analysis, 2:371
 schematic diagram, 2:371f
 lectins, 2:704–705
 microautophagy, 1:150
 microbial electrolysis cell (MEC), 4:74–75,
 4:75f
 microfilaments, 3:233
 microglia, 1:369, 1:370f, 1:371–373
 microglobulins, 1:101t
 microRNA (miRNA), 3:98–102, 4:191–194
 biogenesis, 3:99–100, 3:99f, 4:191, 4:192f
 biological role, 3:101–102
 cardiac muscle development, 1:185
 characteristics, 3:98
 exosomes and microvesicles (EMVs),
 2:262–263
 functional role
 gene transcription regulation, 4:68,
 4:191
 glucose metabolism/insulin signaling,
 4:193, 4:194t
 lipid metabolism, 4:192–193, 4:194t
 metabolic disease treatment, 4:193,
 4:194t
 pancreatic β -cell function, 4:191–192,
 4:194t
 RNA-induced silencing complex (RISC),
 3:100, 3:101f
 historical research, 3:98–99
 hypoxia inducible factor (HIF), 4:68
 RNA editing, 4:155
 RNA-induced silencing complex (RISC),
 3:98, 3:99f, 3:101f
 RNA trafficking, 3:322
 skeletal muscle development, 1:182–183
 microsomal triglyceride transfer protein
 (MTTP), 4:548
 microtubule-associated proteins (MAPs),
 3:103–107
 bundle formation, 3:105–106, 3:106f
 classical MAPs
 characteristics, 3:103, 3:104t
 filamentous structures, 3:104f,
 3:105–106
 MAP1A/MAP1B, 3:103–104, 3:104t,
 3:105f, 3:106–107
 MAP2A/MAP2B/MAP2C, 3:104–105,
 3:104t, 3:105f, 3:106–107, 3:106f
 MAP4, 3:104t, 3:105, 3:105f
 microtubule-actin cross-linking factor
 (MACF), 3:105f, 3:107
 microtubule-based motor proteins, 4:208,
 4:208f
 neurite outgrowth, 3:105–106
 neurodegenerative diseases, 3:106–107
 plakin family, 3:105f, 3:107
 regulatory mechanisms, 3:105
 tau proteins, 3:104t, 3:105, 3:105f,
 3:106–107, 3:106f
 transgenic and knockout mice, 3:106–107
 tubulin isoforms, 4:450
 microtubules, 1:430–431, 1:431f, 3:233,
 4:214, 4:215f
 microvascular disease, 1:655–656
 microvesicles
 See exosomes and microvesicles (EMVs)
 microvillar inclusion disease, 3:223t
 microvilli, 1:35
 milk, 4:533t
 Miller syndrome, 3:713–714
 miniature inverted repeat transposable
 elements, 3:276, 3:276f, 3:281

- mini-chromosome maintenance (MCM)

- respiratory chain complex I (NADH: ubiquinone oxidoreductase), 1:488f, 4:87, 4:91
- phosphate-transfer reactions, 2:580, 2:581f
- phosphofructokinase-2/fructose bisphosphatase-2 (PFK-2/FBPase-2)-activated phosphorylation, 3:457–458, 3:458f
- PKA-mediated lipolysis, 1:49–51, 1:50f, 4:303–304
- plant mitochondrial electron transport chain, 1:141–142, 1:142f
- protein kinase C (PKC), 3:637–638, 3:638f
- protein tyrosine phosphatase (PTP), 3:648, 4:294–295, 4:296f
- pyruvate dehydrogenase kinase (PDK) regulation, 4:324–326, 4:325f
- retinoblastoma protein (pRB), 4:105
- sarcoendoplasmic reticulum Ca²⁺ ATPase (SERCA), 2:228–229
- sodium–potassium (Na⁺–K⁺)-ATPase pump, 3:682–685
- somatostatin (sst) receptors, 4:263–264, 4:263t
- Src (sarcoma) family kinases, 4:295–297, 4:296f
- steroid/thyroid hormone receptors, 4:312
- sugar phosphorylation, 2:543
- translation initiation factor 2 (eIF2 α) phosphorylation, 4:491
- tyrosine, 2:620–621, 2:620f, 2:622f, 4:61
- voltage-gated calcium channels, 4:561
- phosphosphingolipids, 4:282, 4:282f
- phosphotransacetylase, 4:74f

- phosphotransferase system (PTS)
 classification, 2:387
 components, 2:387, 2:388f
 functional role, 2:387, 2:388f
 inositol phosphatases/inositol phosphate kinases, 2:581–582, 2:581f
 preferential glucose utilization, 2:387–388
 phosphotyrosine binding (PTB) domain, 2:603–606
Photinus pyralis, 2:290–291
Photobacterium phosphoreum, 3:666
 photofermentation, 4:74, 4:75f
 photoinhibition, 3:482–487
 basic concepts, 3:484
 charge recombination yield, 3:485
 D1 protein degradation, 3:484–485
 molecular mechanisms, 3:485
 proteases, 3:484
 photolithoautotrophs, 1:488t
 photolithotrophs, 1:488t
 photon migration, 4:279
 photoorganotrophs, 1:488t
 photoreceptors, 3:488–491
 characteristics, 3:488
 deep-brain photoreceptors, 3:491
 nonrod/noncone photoreceptors, 3:490, 3:490f
 parietal-eye photoreceptor, 3:490
 phospholipase D (PLD), 3:473–474
 phototransduction mechanisms, 3:489–490, 3:489f
 pineal photoreceptors, 3:490
 retinal photoreceptors
 characteristics, 3:488
 color vision, 1:550, 1:551f
 cones, 3:488, 3:489f
 rods
 cell body, 3:488, 3:489f
 inner segment, 3:488, 3:489f
 morphology, 3:488, 3:489f
 outer segment, 3:488, 3:489f
 synaptic terminal, 3:488, 3:489f
 photosynthesis, 3:492–496
 adenosine triphosphate (ATP) synthesis, 1:511–512, 1:512f, 3:493–494, 3:494f
 antenna complexes, 3:484f
 basic concepts, 2:335
 carbon dioxide (CO₂)-concentrating mechanisms
 aquatic photosynthesis, 3:495
 C4 pathways, 3:495, 3:495f
 Crassulacean acid metabolism (CAM) pathway, 3:495–496
 carbon dioxide (CO₂) fixation
 Benson–Calvin cycle, 3:494, 3:494f, 3:495f
 general discussion, 3:494–495
 photorespiration, 3:494–495
 electron transport mechanisms, 3:493–494, 3:493f, 3:494f
 light harvesting process, 2:178–183
 antenna complexes, 2:726–727, 3:484, 3:484f

- plakoglobin, 1:257, 1:259t, 1:636–639
- plakophilin, 1:257, 1:258f, 1:636–639, 1:637f
- plant glycoproteins, 2:465–468
 functional role analyses
 future research areas, 2:467
 genetic studies, 2:467
 immunohistochemistry, 2:467
 structural studies, 2:467
- glycan classifications
 N-linked glycans, 2:465, 2:466f
 O-linked glycans, 2:465, 2:466f
- multigene families, 2:467
- O-linked glycans
 characteristics, 2:465, 2:466f
 synthetic pathways
 glycosyl transferases, 2:466
 hydroxyproline residue arrangement effects, 2:466, 2:466f, 2:467f
 proline hydroxylation, 2:465
- plant lectin binding analyses, 2:460–461
- plants
 antenna complexes, 3:484, 3:484f
 aquaporin water channels, 1:125
- ascorbic acid, 4:532
- ATP synthesis, 1:141–144
 background information, 1:141
 glycine decarboxylase, 1:142–143
 inhibitors, 1:143, 1:143t
 mitochondrial electron transport chain, 1:141–142, 1:142f
 substrates, 1:142–143
- uncoupling processes
 alternative NAD(P)H dehydrogenases, 1:144
 alternative oxidases (AOXs), 1:144
 chemical uncouplers, 1:143
 nonphosphorylating respiration, 1:142f, 1:144
 uncoupling proteins (UCPs), 1:142f, 1:144
- brassinosteroids (BRs), 1:250–254
 background and characteristics, 1:250
- biosynthetic pathway
 campesterol-to-brassinolide pathway, 1:251, 1:252f
 cycloartenol-to-campesterol pathway, 1:251
 general discussion, 1:250–251
 mevalonic acid-to-cycloartenol pathway, 1:250–251
- chemical structure, 1:250, 1:251f
- endogenous levels, 1:250
- occurrences, 1:250
- physiological characteristics, 1:252
- research background, 1:250
- signal transduction
 characteristics, 1:252–254
 downstream activators, 1:254
 receptor kinases, 1:253–254, 1:253f
- calpains, 1:354f
- copper-transporting ATPases (copper pumps), 3:671–672
- cytochrome *c*, 1:600, 1:600f
- cytokinins, 1:627–631
 background information, 1:627
 biosynthesis, 1:627–628
 chemical structure, 1:627, 1:628f
 functional roles
 biotechnological applications, 1:631
 cell cycle, 1:629
 pathogenicity, 1:631
 plant development and growth, 1:629–630
- metabolism
 catabolic reactions, 1:629
 conjugations, 1:628–629
 cytokinin oxidases/dehydrogenases (CKX), 1:629

 liver PK (LPK) *in vitro* regulation, 3:719
 negative feedback, 1:578–579, 1:578*f*
 neurogenesis, 1:199
 Perilipin 1 (Plin1), 1:47–48, 1:48*f*
 phosphofructokinase-2/fructose biphosphatase-2 (PFK-2/FBPase-2)
 activation, 3:457–458
 PKA-mediated lipolysis, 1:49–51, 1:50*f*, 4:303–304
 plasma membrane calcium (Ca^{2+})-ATPase pump, 3:525–526
 structural domains, 1:574–575, 1:575*f*, 1:576*f*
 substrate specificity, 1:578
- protein kinase B (PKB)
 functional role, 3:463–464
 glycogen synthase kinase-3 (GSK3), 2:435*f*
 insulin signal transduction, 2:604
- protein kinase C (PKC), 3:637–640
 background information, 3:637
 bile salts, 1:169
 calcium ion (Ca^{2+}) signaling system, 2:719–720, 2:720*f*
 calcium oscillation decoding, 1:325
 calcium-sensing receptor (CaSR), 2:583, 2:584*f*
 chemokine receptors, 1:480–482, 1:482*f*
 diabetes, 1:656
 domain structures, 3:637, 3:638*f*
 downregulation, 3:639
 G_{bg} subunit functions, 1:480–482, 1:482*f*, 4:265
 glycogen synthase kinase-3 (GSK3), 2:435*f*
 G protein-coupled receptor kinases (GRKs), 2:485*t*
 G_q family proteins, 2:497–498, 2:498*f*
 historical research, 3:637
 insulin resistance, 1:650
 insulin-secreting cells (β -cells), 2:597*f*
 insulin signal transduction, 2:604
 isozyme families, 3:637, 3:638*f*
 mitochondrial permeability transition pore, 3:165–166
 neurogenesis, 1:199
 phosphorylation, 3:637–638, 3:638*f*
- plasma membrane calcium (Ca^{2+})-ATPase pump, 3:525–526
- platelet-activating factor receptor (PAFR), 3:536, 3:536*f*
- signaling pathways, 3:639–640
- somatostatin (sst) receptors, 4:265
- store-operated calcium (SOC) channels, 3:359–360, 3:360*f*
- subcellular localization, 3:639
- T-cell receptors (TCRs), 4:374, 4:377–378
- translocation cycle, 3:638–639, 3:639*f*
- protein O-fucosyltransferase I (Pofut1), 2:453, 2:454*f*, 2:456
- protein O-mannosyltransferase (POMT), 2:454, 2:454*f*
- protein phosphatase 1 nuclear-targeting subunit (PNUITS), 1:312
- proteins
- AAA (ATPases associated with various cellular activities) proteins, 1:1–6
- AAA+ superfamily, 1:3–5, 1:3*t*
- basic concepts, 1:1
- cellular functions
- membrane-bound metalloproteases, 1:6
- membrane fusion, 1:5–6
- proteasome-dependent degradation, 1:5
- vesicle transport, 1:5–6
- classifications, 1:3–5, 1:3*t*, 1:4*f*
- dyneins, 2:184–187
- axonemal dyneins, 2:185*t*, 2:186–187
- characteristics and classifications, 2:184, 2:185*t*
- cytoplasmic dynein 1, 2:185–186, 2:185*t*, 2:186*f*
- cytoplasmic dynein 2 (IFT dynein), 2:185*t*, 2:186
- dynein heavy chain, 2:184–185, 2:185*t*, 2:186*f*
- dynein intermediate chain, 2:185*t*, 2:186*f*
- dynein light chain, 2:185*t*, 2:186*f*
- inner arm dyneins, 2:185*t*, 2:187
- outer arm dyneins, 2:185*t*, 2:187
- research summary, 1:6
- structure and functions, 1:1–2, 1:2*f*, 1:3*f*

plant mitochondrial electron transport chain, 1:145, 1:146f

protonmotive electron transfer chain, 1:470f

reverse electron transport (RET), 4:19f, 4:20

schematic diagram, 4:84f, 4:99f

structural characteristics, 4:341–346

- accessory subunits, 4:88, 4:89t
- central subunits, 4:87–88, 4:88f, 4:89t
- cysteine motif, 4:344–345, 4:345f
- flavin mononucleotide (FMN) binding, 4:344–345, 4:344f
- frataxin-like subunit, 4:343–344, 4:343f
- hydrophilic domain, 4:342–343, 4:342f
- iron–sulfur clusters, 4:87–88, 4:89t, 4:342–343, 4:342f, 4:345f
- multistage assembly pathway, 4:88
- mutations, 4:345
- NADH binding, 4:344–345, 4:344f, 4:345f
- overall structure, 4:341–342

redox centers, 4:87–88, 4:89t, 4:342–343, 4:342f

research summary, 4:345–346

shape, 4:87, 4:88f

subunits, 4:342t

supernumerary subunits, 4:345

respiratory electron transport chain, 3:661–662, 3:662f, 3:663, 3:694–695, 3:694f

succinate:quinone oxidoreductases (SQORs), 4:92–97

characteristics and functional role, 4:92, 4:93f

classifications

functional classification, 4:92

structural classification, 4:92–93

electron-coupled proton transfer, 4:96–97, 4:97f

electron transfer, 4:96

facultative phototrophic respiration, 4:79, 4:80f

structure and functions

domain structures, 4:93, 4:94f

flavin adenine dinucleotide (FAD/FADH₂), 4:95, 4:95f

iron–sulfur clusters (FeS), 4:95

quinol oxidation/quinone reduction, 4:95–96

relative orientations, 4:93–94

subunit A, 4:95, 4:95f

subunit B, 4:95

subunits C and D, 4:95–96

succinate oxidation/fumarate reduction, 4:95, 4:95f

thermoplasma-quinone (TK), 4:94f

vitamin K, 3:727–728, 3:728f, 4:552f

quinonoid dihydrobiopterin, 3:666–667, 3:668f

R

rabbits, 2:638t

Rab Escort Protein (REP), 2:737–738

Rab guanosine triphosphatase (GTPase) activating protein (GAP)

Golgi proteins, 2:479

insulin signal transduction, 2:604–605

phosphatidylinositol-3-phosphate (PtdIns(3)P), 3:449

small guanosine phosphatases (GTPases), 4:242, 4:243f, 4:244f

transport pathways, 4:206, 4:504–506, 4:505f

Rab protein family, 4:1–6

cellular localization, 4:2, 4:4f, 4:4t

disease connections, 4:4–6

domain effectors, 4:4

domain structures, 4:1–2, 4:2f

evolutionary development, 4:2

functional cycle, 4:2–4, 4:5f

functional role, 4:4t

phylogenetic relationships, 4:3f

posttranslational modifications, 4:2

research background, 4:1

tissue expression, 4:4t

- Rac1 protein, 1:262–263, 1:263f, 1:430–431, 1:431f, 2:321–322, 2:321f, 4:112f, 4:113t
- Rac2 protein, 4:112f, 4:113t
- Rac3 protein, 4:112f, 4:113t
- radiosensitive severe-combined immune deficiency (RS-SCID) syndrome, 3:273, 3:273t
- radishes, 4:533t
- Rad protein complex
- DNA ligases, 2:30, 2:30t
 - DNA-strand transferases, 4:37, 4:37f, 4:38f
 - Homo sapiens* 9–1–1 clamp, 4:239, 4:239f
 - Homo sapiens* PCNA, 4:239f
 - meiotic recombination, 2:557–558, 2:559f
 - non-homologous end joining (NHEJ), 3:272
 - nucleotide excision repair (NER), 3:338f, 3:341–342, 3:342t, 3:343f, 4:404
 - polymerase α -primase (Pol α), 2:243–244
- Rad50 protein, 3:272
- recombination-dependent DNA replication (RDR), 4:24–25, 4:31–32
- Raf kinases, 1:480–482, 1:482f, 2:528f, 4:247–248, 4:247f
- RAG1/RAG2 proteins, 3:272, 3:272f
- RAGE (receptor for advanced glycation end products), 2:407–409
- ragged red fiber disease, 1:211f, 1:214
- Ralstonia eutropha*, 4:89
- raltegravir, 2:106f
- Ramakrishnan, Venkatraman, 2:254
- Raman spectroscopy, 2:661–662
- RanBP2, 4:468t, 4:469
- ranibizumab, 3:431
- RANK/RANKL receptor proteins, 3:385–386, 4:459
- Ran protein family, 4:7–11
- cellular gradient, 4:8, 4:9f, 4:10f
 - chromatin regulation function, 4:10
 - domain structures, 4:244f
 - functional role, 4:7, 4:243f
 - mitotic spindle regulation, 4:9–10
 - molecular switches, 4:7
 - nuclear envelope assembly regulation, 4:9–10
 - nuclear transport, 4:8–9, 4:10f
 - nucleocytoplasmic transport, 4:7, 4:8f
- RanGAP (GTPase-stimulating protein), 4:8, 4:9f, 4:10f
- RanGEF (guanine nucleotide exchange factor), 4:8, 4:9f
- Ranunculus*, 1:509f
- RAPADILINO, 4:46
- rapamycin (mTOR), 3:194–199
- background information, 3:194
 - branched-chain amino acids (BCAAs), 1:246f

 redox centers, 4:87–88, 4:89t,
 4:342–343, 4:342f
 research summary, 4:345–346
 shape, 4:87, 4:88f
 subunits, 4:342t
 supernumerary subunits, 4:345
 respiratory chain complex II (succinate
 coenzyme Q reductase)
 background information, 4:98
 biochemical free radical chain reactions,
 3:170f, 3:172f, 3:173f
 coenzyme Q, 3:724–725, 3:724f, 4:18–20,
 4:19f
 inhibitors, 1:143, 1:143t
 mitochondrial ROS, 4:19f, 4:20
 PET genes, 3:308f
 plant mitochondrial electron transport
 chain, 1:145, 1:146f
 protonmotive electron transfer chain,
 1:470–471, 1:470f
 schematic diagram, 4:84f, 4:99f
 succinate:quinone oxidoreductases
 (SQORs), 4:92–97
 characteristics and functional role, 4:92,
 4:93f
 classifications
 functional classification, 4:92
 structural classification, 4:92–93
 electron-coupled proton transfer,
 4:96–97, 4:97f
 electron transfer, 4:96
 facultative phototrophic respiration,
 4:79, 4:80f
 structure and functions
 domain structures, 4:93, 4:94f
 flavin adenine dinucleotide (FAD/
 FADH₂), 4:95, 4:95f
 iron–sulfur clusters (FeS), 4:95
 quinol oxidation/quinone reduction,
 4:95–96
 relative orientations, 4:93–94
 subunit A, 4:95, 4:95f
 subunit B, 4:95
 subunits C and D, 4:95–96
 succinate oxidation/fumarate
 reduction, 4:95, 4:95f
 UCP1-induced proton cycling, 4:484f
 respiratory chain complexes, 4:83–86
 complex characteristics and functions
- respiratory chain complex I (NADH:
 ubiquinone oxidoreductase),
 4:83–84
 respiratory chain complex III (ubiquinol
 cytochrome *c* reductase), 4:84, 4:84f
 respiratory chain complex IV
 (cytochrome *c* oxidase), 4:84
 schematic diagram, 4:84f
 components
 cytochromes, 4:83
 flavins, 4:83
 general discussion, 4:83
 iron–sulfur (FeS) proteins, 4:83
 ubiquinone, 4:83
 organization, 4:85
 PET genes, 3:307–309, 3:308f
 ubiquinol-oxidizing enzymes, 4:85
 ubiquinone-reducing enzymes
 electron-transferring flavoprotein (ETF)–
 ubiquinone oxidoreductase, 4:85
 external NADH dehydrogenase, 4:85
 general discussion, 4:85
 glycerol-3-phosphate dehydrogenase,
 4:85
 succinate dehydrogenase, 4:85
 respiratory chain complex III (ubiquinol
 cytochrome *c* reductase), 1:593–598
 action mechanisms
 inhibitors, 1:598
 proton conduction pathways,
 1:597–598, 1:597f
 protonmotive Q cycle, 1:596–597,
 1:597f, 3:663–664, 3:664f
 anoxygenic photosynthesis, 3:694f
 background information, 4:98
 basic concepts, 1:593
 biochemical free radical chain reactions,
 3:170f, 3:172f, 3:173f
 coenzyme Q, 3:724–725, 3:724f, 4:18–20,
 4:19f
 cytochrome *c* interactions, 1:601, 1:601f
 electron transfer complexes, 3:695, 4:93f
 facultative phototrophic respiration, 4:79,
 4:80f
 functional role, 1:593, 1:594f, 4:84
 inhibitors, 1:143, 1:143t
 mitochondrial ROS, 4:19f, 4:20
 oxygen respiration, 3:30–31
 periplasmic electron-transport systems,
 3:400, 3:401f
 PET genes, 3:308f
 photosynthesis/respiration, 3:695
 photosynthetic reaction centers,

sodium ion/calcium ion ($\text{Na}^+/\text{Ca}^{2+}$) exchanger
functional role, 3:47
gene families, 3:45
historical research, 3:44
NCX/NCKX expression, 3:45–46
physiological functions, 3:48
voltage-gated calcium channels, 4:561t
retinaldehyde, 3:489–490, 3:489f
retinal dehydrogenases (Raldh), 4:525
retinitis pigmentosa, 1:584
retinoblastoma protein (pRB), 4:104–107
cell–cycle regulation, 1:406–407, 1:407f, 4:105
cellular functions, 4:105
E2F transcription factor, 1:406–407, 1:407f, 4:106–107
functional role, 4:104
future research areas, 4:106
 G_0 phase and G_1 phase cell-cycle regulation, 1:406–407, 1:407f
molecular functions, 4:106–107
pRB-related proteins, 4:104
RB1 tumor suppressor gene, 1:406–407, 1:407f, 4:104–105
regulatory pathways, 4:105–106
9-cis-retinoic acid (9cRA), 3:418–419, 4:525
retinoic acid receptors, 4:108–110
background information, 4:108
domain structures, 4:108, 4:109f
functional role, 4:109–110
functional roles, 4:525
hematopoiesis, 1:188–189
naturally occurring retinoids, 4:529
- peroxisome proliferator-activated receptors (PPARs), 3:418–419, 3:420f, 3:422f
retinoic acid receptor α (RAR α), 1:188–189, 4:109–110
retinoic acid receptor β (RAR β), 4:109–110
retinoic acid receptor γ (RAR γ), 4:109–110
retinoic acid response elements (RAREs), 4:109
retinoid metabolic pathways, 4:527f
signaling pathways, 4:108
structure and functions
C-terminus regions, 4:109
DNA-binding domain, 4:108
general discussion, 4:108–109
N-terminus regions, 4:109
retinoic acid (RA)-binding domain, 4:108–109
transcriptional activation, 4:109, 4:110f
retinoids, 4:525–529
chemical and metabolic reactions, 4:525–526, 4:526t
clinical uses, 4:529
functional roles, 4:525
homeostasis control mechanisms, 4:529
naturally occurring retinoids, 4:529
pharmacological retinoid concentrations, 4:528–529
retinoid-binding proteins (RBPs), 4:526–528, 4:527f, 4:527t
retinoid homeostasis, 4:526–528
retinoid X receptor (RXR)
endoplasmic reticulum (ER), 4:207
insulin signal transduction, 2:604–605, 2:604f
mucins, 3:208f
secretory pathway, 4:207
steroid/thyroid hormone action
mechanisms, 4:308–309, 4:310f
vitamin D receptor (VDR), 4:540, 4:541f
vitamin D-response elements (VDREs), 4:537–538, 4:538f, 4:540, 4:541f, 4:542–543
retinol dehydrogenases (RDHs), 4:525, 4:526t, 4:527f
retinyl ester, 1:49–51
retinyl ester hydrolase (REH), 4:525
retrotransposons, 3:283–291
classifications and characteristics, 3:283, 3:284f
diversity-generating retroelements (DGRs), 3:284
extra-chromosomally-primed (EP) retrotransposons
characteristics, 3:284
integration site preference, 3:288
long terminal repeat (LTR)
retrotransposons, 3:284–286, 3:285f, 3:286f, 3:287f

Saccharomyces cerevisiae (Continued)

exon–intron architecture, 3:142–144, 3:143f, 4:186–187
 extra-chromosomally-primed (EP) retrotransposons, 3:285f
 fermentation reactions, 2:205t
 flippase-mediated transbilayer movement, 2:315–316
 free oligosaccharides (fOSs), 2:331
 GAL1–10 gene expression, 1:525
 glutathione peroxidases, 2:402f
 glycosylphosphatidylinositol (GPI)-anchored proteins, 2:478
 G-protein-signaling regulators (RGSs), 2:492
 GroEL (growth E locus, large gene, bacterial group I chaperonin), 1:459
 heterotrophic glutathione reductase (GR)-type FNRs, 2:301
 hexameric enzyme helicases, 2:22
 hexokinases, 2:543–544, 2:544t, 2:545f
 isoprenylcysteine methyltransferase (ICMT), 3:608–609
 kinesin superfamily proteins (KIFs), 2:679–681, 2:682f
 macroautophagy
 Atg proteins, 1:151–153, 1:152t
 cytoplasm-to-vacuole targeting (Cvt) pathway, 1:151, 1:151f
 model systems, 1:150–151
 molecular mechanisms, 1:151–153
 Atg proteins, 1:151–153, 1:152t
 cargo selection, 1:153
 fusion and breakdown, 1:153
 phagophore assembly site (PAS), 1:152
 regulatory mechanisms, 1:152–153
 meiotic loop–axis structure, 3:21f
 microautophagy
 mitophagy, 1:153
 nonselective microautophagy, 1:153
 pexophagy, 1:153
 mitochondrial DNA (mtDNA)
 functional role, 3:132
 gene expression, 3:140–144
 basic process, 3:140–141, 3:141f
 encoding processes, 3:140
 5′-end–RNase P process pathway, 3:142, 3:142f
 model systems, 3:140, 3:141f
 mosaic mitochondrial genes, 3:142–144, 3:143f
 RNA splicing, 3:142–144, 3:143f
 3′-end–RNase process pathway, 3:142, 3:142f
 transcription processes, 3:141, 3:141f, 3:142f
 translation processes, 3:144
 sequence and gene content, 3:133t
 multidrug resistance (MDR) membrane proteins, 3:214
 N-myristoyltransferase (Nmt), 3:642–643, 3:643f
 nucleoporin proteins (Nups), 3:319f, 3:320t
 nucleotide excision repair (NER), 3:341, 3:342f, 3:342t

origin recognition complex (ORC), 2:111
 peptide amidation, 3:398
 peroxisomal matrix protein import, 3:426–429
PET genes
 model systems, 3:307
 number of proteins, 3:307
 pheromone receptors, 3:441–446
 conformational constraints, 3:445
 conjugation functions, 3:441, 3:442f
 G-protein activation, 3:445–446
 ligand binding, 3:444–445
 receptor biogenesis, 3:443–444, 3:444f
 regulatory mechanisms, 3:442–443, 3:443f, 3:444f
 signal transduction pathways, 3:441–442, 3:443f
 spatial gradient sensors, 3:442
 phosphodiesterases (PDEs), 1:572
 phospholipase D (PLD), 3:473
 phospholipid synthesis, 3:478–481
 basic process, 3:478
 cytidine diphosphate (CDP)–choline pathway, 3:479f, 3:480
 cytidine diphosphate (CDP)–diacylglycerol (DAG) pathway, 3:478–480, 3:479f
 cytidine diphosphate (CDP)–ethanolamine pathway, 3:479f, 3:480
 major phospholipids, 3:478, 3:479f
 phosphatidate (PA) synthesis, 3:478
 phosphatidylglycerolphosphate (PGP), 3:480
 regulation mechanisms
 biochemical regulation, 3:481
 general discussion, 3:480
 genetic regulation, 3:480–481
 plasma membrane proton (H⁺)-ATPases, 3:688
 polymerase δ (Pol δ), 1:402t, 2:245–246, 2:246f, 2:246t
 prions, 3:566, 3:568–569
 protein biosynthesis elongation, 2:253
 proteolysis, 4:62
 recombination-dependent DNA replication (RDR), 4:24–25
 RecQ helicases, 4:43–44, 4:44f, 4:45, 4:47–49
 retrotransposons, 3:283, 3:284f
 rhomboid-based mediation, 4:51f
 ribosomal RNA (rRNA)
 pre-ribosomal intermediates, 4:118–119, 4:119f, 4:120f
 synthesis and processing, 4:117–118, 4:118f
 septins, 4:216–217, 4:216f
 sliding clamp processivity
 9–1–1 complex, 4:239, 4:239f
 proliferating cell nuclear antigen (PCNA), 4:236–237, 4:237f, 4:239, 4:239f, 4:240f
 S phase initiation proteins, 1:401, 1:402t
 sugar nucleotide transporters, 4:350
 superoxide dismutases (SODs), 4:353

telomere proteins, 4:382–384
 3-methyladenine (3mA) DNA glycolase II, 2:11
 translocation cycle, 2:252
 TRiC/CCT eukaryotic chaperonin, 1:459
 20S proteasome, 3:591f
 tyrosine recombinases, 1:556–557
 vacuoles
 biogenesis, 4:503–506
 characteristics, 4:502–503
 functional role, 4:503, 4:504f
 transport pathways
 AP-3 pathway, 4:505f, 4:506
 autophagy/macro-autophagy, 4:505f, 4:506, 4:506f
 characteristics, 4:503–506, 4:505f
 Vps pathway, 4:504–506, 4:506f
Saccharomyces chevalieri, 1:125
Saccharomyces pombe, 2:22
Saccharopolyspora, 1:319t
 S-adenosylhomocysteine (SAH), 3:607, 3:608f
 S-adenosylmethionine (SAM)
 bacteriochlorophyll (BChl) biosynthesis, 2:503–504
 brassinosteroid biosynthesis, 1:251
 carboxyl methylation, 3:607, 3:608f, 3:609f
 DNA alkylation damage, 2:9
 DNA methylation, 3:6
 [FeFe]-hydrogenases, 4:72
 iron–sulfur clusters (FeS), 2:660, 2:661f
 protoporphyrinogen IX, 2:541
 riboswitches, 4:137, 4:138f, 4:251
 salicylhydroxamic acid (SHAM), 1:145–146
 salivary glands
 aquaporin water channels, 1:124t
 digestion and absorption, 2:354
 salmeterol, 1:59
Salmonella
 Dam methylation, 2:43
 nuclear factor kappa B (NF- κ B), 3:303t
 vacuole/lysosome functions, 4:507
Salmonella enterica
 Dam methylation, 2:43
 fatty acyl-coenzyme A (CoA) synthetases, 2:294–295
 type I DNA restriction and modification enzymes, 2:72–74
Salmonella typhi
 macropinocytosis, 2:199
 3-methyladenine (3mA) DNA glycolase I, 2:10–11, 2:11f
Salmonella typhimurium
 Cho phylogenetic tree, 3:331f
 mismatch repair (MMR), 2:54
 phosphotransferase system (PTS), 2:387
 site-specific recombination systems, 1:555–556
 type III DNA restriction and modification enzymes, 2:137t

Rab protein family, 4:1–6
cellular localization, 4:2, 4:4f, 4:4t
disease connections, 4:4–6
domain effectors, 4:4
domain structures, 4:1–2, 4:2f
evolutionary development, 4:2
functional cycle, 4:2–4, 4:5f
functional role, 4:4t
phylogenetic relationships, 4:3f
posttranslational modifications, 4:2
research background, 4:1
tissue expression, 4:4t
Ran protein family, 4:7–11
cellular gradient, 4:8, 4:9f, 4:10f
chromatin regulation function, 4:10
domain structures, 4:244f
functional role, 4:7, 4:243f
mitotic spindle regulation, 4:9–10
molecular switches, 4:7
nuclear envelope assembly regulation, 4:9–10
nuclear transport, 4:8–9, 4:10f
nucleocytoplasmic transport, 4:7, 4:8f
RanGAP (GTPase-stimulating protein), 4:8, 4:9f, 4:10f
RanGEF (guanine nucleotide exchange factor), 4:8, 4:9f
small GTPase Ran, 3:320–321, 3:321f, 4:7, 4:8f
regulation mechanisms, 4:245
research background, 4:242
signaling cascades, 4:245–246, 4:246f
small intestine
bile acid secretion and absorption, 2:358
carbohydrate digestion and absorption, 2:359
digestion processes, 2:355f
intestinal pH, 2:357
lipid digestion and absorption
cholesterol, 2:358
phospholipids, 2:358
triglyceride (TG), 2:358
nutrient transit, 2:356–357
pancreatic exocrine secretion, 2:357–358, 2:357f
protein digestion and absorption, 2:358–359
small nuclear RNAs (snRNAs)
basic concepts, 3:59–60, 3:60f
intronic splicing silencers (ISSs), 3:62f
mitochondrial gene expression, 3:142–144
RNA-binding proteins, 3:62–63
RNA trafficking, 3:322
spliceosomes, 4:187
small nuclear RNP (snRNP) complexes, 1:75, 1:76f, 1:78f
small RNAs (sRNAs), 4:249–255
ARGONAUTE (AGO) protein, 4:253–255
bacterial decay, 3:57, 3:57f, 4:249–250
characteristics, 4:249–250
cis-acting riboswitches
characteristics, 4:250–251
RNA ligand sensors, 4:250f, 4:251
RNA thermosensors, 4:250, 4:250f
cis-encoded RNAs, 4:251, 4:252f
clustered regularly interspaced short palindromic repeat (CRISPR) RNAs (crRNAs), 4:253, 4:254f
microRNA (miRNA), 3:98
nucleic acid-binding protein (NABP), 4:252–253, 4:252f
protein modulation, 4:252–253
research summary, 4:255
trans-encoded RNAs, 4:251–252, 4:252f
small ubiquitin-related modifiers (SUMOs), 3:191–192, 4:69, 4:468–470, 4:468t, 4:475
smooth muscles
actin organization, 1:32–33
smooth muscle contraction, 1:32–33, 2:642
smooth muscle myosin light chain kinase (smMLCK), 1:32–33, 1:305–306, 1:305f
voltage-gated calcium channels, 4:561t
snails
lectins, 2:702t
vasopressin/oxytocin family, 4:516t
SNARE proteins, 4:206, 4:504–506, 4:505f
Snell's Waltzer mouse, 3:223–224
SNIP1 protein, 3:99–100
snowdrops, 2:702t, 2:704t
SNX proteins, 3:449
SOD enzyme, 4:21
sodium-ascorbate co-transporters (SVCT1/2), 4:532–533
sodium-dependent glucose transporters (SGLTs), 2:391, 2:392f
sodium/galactose transport (SglT), 2:388, 2:389, 2:389f
sodium (Na), 4:161
sodium benzoate, 4:495–497, 4:497t
sodium dodecyl sulfate, 1:644–645, 1:645f
sodium ion/calcium ion (Na⁺/Ca²⁺) exchanger, 3:44–48
calcium ion (Ca²⁺)-binding domains, 4:257f, 4:259–260, 4:260f
calpains, 1:424, 1:425f
cellular calcium ion (Ca²⁺) homeostasis, 1:290, 3:44
cytoplasmic domain structure–function relationship
calcium ion (Ca²⁺)-binding domains, 4:257f, 4:259–260, 4:260f
C-terminus regions, 4:261
cytoplasmic loop f, 4:258
cytoplasmic loops b and d, 4:260–261
exchanger inhibitory peptide region, 4:258–259, 4:259f
linker domain 1, 4:259
linker domain 2, 4:260
Na⁺-dependent inactivation, 4:258–259, 4:259f
excitotoxicity, 1:424, 1:425f
functional role, 3:47, 3:47f, 4:256
gene families, 3:45, 3:45f, 3:46f
historical research, 3:44
mitochondrial calcium (Ca²⁺) transport, 3:125–126
NCLX protein superfamily, 3:125
NCX1 dimerization, 4:257–258
NCX1 helix packing, 4:256–257, 4:258f
NCX1 membrane topology, 4:256, 4:257f
NCX extracellular domain
structure–function relationship, 4:261
NCX/NCKX expression, 1:380f, 1:381–382, 1:382f, 3:45–46, 3:45f, 3:46f
phosphatidylinositol-4,5-bisphosphate (PIP₂), 2:746–747
phototransduction mechanisms, 3:489–490, 3:489f
physiological functions, 3:48
structural characteristics, 3:45f, 3:46–47, 4:256–261
topology model, 3:45f
transmembrane domain function, 4:257–258, 4:258f
transmembrane segments, 4:256, 4:258f
sodium ion (Na⁺) pumping, 4:90
Na⁺ translocation, 2:206–208, 2:208f
sodium phenylacetate, 4:495–497, 4:497t
sodium-potassium-chlorine (Na-K-Cl) cotransporter isoform 1 (NKCC1), 1:199, 1:200f
sodium–potassium (Na⁺–K⁺)-ATPase pump, 3:681–687, 3:688–692
cardiac glycosides, 3:686–687, 3:686f, 3:687f
characteristics and functional role, 3:681, 4:331–333
domain structures, 4:333f
FXYD proteins, 3:681, 3:682–685, 3:682t, 3:683f
physiological functions, 3:685–686
reaction mechanisms, 3:683, 3:682
structural characteristics
 α subunits, 3:683–684, 3:684f
 β subunits, 3:683f, 3:684–685
cation-pumping mechanism, 3:683–684, 3:684f
domain structures, 3:683–684, 3:683f, 4:333f
FXYD proteins, 3:682–685, 3:683f
schematic diagram, 3:684f
subunits and isoforms, 3:683f
subunits and isoforms, 3:681, 3:682t, 3:683f
voltage-gated sodium channels, 4:564–569
cardiac excitation–contraction (E–C) coupling, 1:379, 1:380f
evolutionary development, 4:564–565
functional role, 2:648–649, 4:564

- catalytic iron-sulfur clusters (FeS), 2:660–661, 2:661f
 - electron transfer, 2:660
 - free-radical reactions, 2:660
 - protein structure stabilization, 2:660
 - reducing powers, 2:660
 - regulatory functions, 2:661
 - sensing functions, 2:661
 - iron-sulfur clusters (FeS)
 - characteristics and functional role, 2:335–336, 2:336f
 - electronic structure, 2:657–658
 - F_x and F_b clusters, 2:338–339
 - F_x- and F_b-containing proteins, 2:339–340, 2:339f
 - ferredoxins (Fd), 2:297–298, 2:301f, 2:661f, 3:485, 3:505, 3:505f
 - frataxin functions, 2:333
 - F_x cluster, 2:338, 2:338f
 - magnetic characteristics, 2:657–658
 - nomenclature, 2:657
 - respiratory chain complex I (NADH: ubiquinone oxidoreductase), 4:342–343, 4:342f, 4:345f
 - respiratory chain complex III, 1:596, 1:596f, 3:663–664, 3:664f
 - stability, 2:657
 - structural characteristics, 2:657, 2:658f
 - succinate:quinone oxidoreductases (SQORs), 4:95
 - type I reaction centers, 2:335–342
 - nomenclature, 2:658
 - respiratory chain complexes, 4:83
 - Rieske protein
 - cytochrome *b₆*f complex, 2:335, 4:335–338, 4:337f, 4:338t, 4:339t
 - cytochrome *bc₁* complex, 1:596, 1:596f, 3:30–31, 3:663–664, 3:664f
 - cytochrome *f*, 3:32
 - posttranslational modifications, 4:338
 - protonmotive Q cycle, 3:663–664, 3:664f
 - structural characteristics
 - flexibility, 2:659–660
 - higher-order structures, 2:659
 - metallic superclusters, 2:659, 2:659f
 - primary structures, 2:658
 - secondary structures, 2:658–659
 - tertiary structures, 2:658–659
 - purple bacteria electron acceptors and donors, 3:698, 3:698t
 - sulfate respiration, 2:206, 2:207f
 - sulfite oxidase, 3:116
- sulindac, 3:305t
- sumoylation, 4:62
- SUN domain proteins, 3:314, 3:315f
- Sup35 protein
 - characteristics, 3:566
 - disease states, 3:568–569
 - generation mechanisms, 3:569
 - prion domains, 3:568f
 - self-propagating amyloidoses, 3:567–568, 3:568f
- superoxide anion (O₂)
- biochemical free radical chain reactions, 3:168–169, 3:169f
 - mitochondrial production, 3:169–170, 3:170f, 3:171f, 3:173f
 - physiological functions, 3:172–173
 - superoxide dismutases (SODs), 4:352–354
 - amyotrophic lateral sclerosis (ALS), 4:354
 - cellular respiration, 3:407, 3:408f
 - deletion consequences
 - Escherichia coli*, 4:353
 - mice, 4:354
 - Saccharomyces cerevisiae*, 4:353
 - enzyme families
 - action mechanisms, 4:352
 - copper SODs, 4:352–353
 - iron SODs, 4:353
 - manganese SODs, 4:353
 - zinc SODs, 4:352–353
 - functional role, 4:352
 - historical research, 3:168–169
 - mitochondrial DNA (mtDNA), 1:212f
 - mitochondrial production, 3:171f, 3:173f
 - nuclear factor kappa B (NF-κB), 3:304t
 - pharmaceutical mimics, 4:354
 - photosystem I (PSI) complex, 3:485
 - prion protein (PrP), 3:574
 - regulation mechanisms, 2:77
 - suppressor of cytokine signaling-3 (SOCS-3), 2:260, 2:260f, 2:526, 2:528f
 - supra-molecular activation clusters (SMACs), 4:376
 - surfactant proteins (SPs), 2:703–704, 2:704t
 - survival of motor neuron (SMN) gems, 3:300–301, 3:300f
 - Su(var)3–9, Enhancer-of-zeste, Trithorax (SET) domain, 4:60–61
 - swainsonine (SW), 2:459f
 - sweat glands, 1:124t, 2:669t
 - sweet taste receptors, 4:366–367
 - Swi1p protein, 3:566
 - swiholide A, 1:16, 1:16t
 - [SWI+] prion
 - See* prions
 - Swiss Institute of Bioinformatics (SIB), 3:611–612
 - SWItching defective/Sucrose NonFermenting (SWI/SNF) family, 1:314, 4:60f, 4:63–64, 4:403–404

T

- T7 RNA polymerase, 4:355–359
- applications, 4:359
 - polymerase sequence similarities, 4:355–357, 4:356f, 4:357f
 - structural characteristics, 4:355, 4:356f
 - structure–function relationship, 4:355, 4:357f
 - transcription reaction/conformational change
 - DNA replication priming, 4:359
 - initial transcription reaction, 4:356f, 4:357–358
 - pausing or terminator sites, 4:356f, 4:358, 4:358f
 - process mechanisms, 4:356f, 4:359
 - promoter release and elongation, 4:356f, 4:358
 - promoter structure, recognition, and opening, 4:357, 4:358f
 - regulation mechanisms, 4:356f, 4:358–359
- tachykinins, 4:360–365
- basic concepts, 4:360
 - G_q family proteins, 2:497t
 - hemokinin 1, 4:361, 4:361f
 - neurokinin-1 receptor (NK1R)
 - carboxyl tail, 4:363–364, 4:363f
 - disease connections
 - affective disorders, 4:364–365
 - depression, 4:364–365
 - emesis, 4:364
 - glioblastomas, 4:365
 - research background, 4:364–365, 4:364f
 - full-length NK1R, 4:361–363, 4:362f
 - functional role, 4:361, 4:362f
 - truncated NK1R, 4:363
 - neurokinin A, 4:360–361, 4:361f, 4:364f
 - neurokinin B, 4:361, 4:361f, 4:364f
 - substance P, 4:360, 4:361f, 4:364f
- tadalafil, 1:569
- talin, 2:609f, 2:610–611, 3:438–439

- tamsulosin, 1:58
- tandem (MS/MS) mass spectrometry, 3:12, 3:12f, 3:14f
- tangle-only dementia, 1:477t
- target-primed (TP) retrotransposons
- characteristics, 3:284
 - integration site preference, 3:288–289
 - long interspersed elements (LINEs), 3:284, 3:285f, 3:287–288
 - organellar retrotransposons, 3:288
 - Penelope-like elements (PLEs), 3:284, 3:285f, 3:288
 - prokaryotic retrotransposons, 3:288
 - R2-type elements, 3:287, 3:287f
 - short interspersed elements (SINEs), 3:285f, 3:287–288
- target recognition domain (TRD)
- DNA methyltransferases (MTases), 3:8–9, 3:8f
 - type I DNA restriction and modification enzymes, 2:72–73, 2:73f
 - type III DNA restriction and modification enzymes, 2:137–138
- taste receptors, 4:366–368
- bitter taste receptors, 4:367
 - G-protein-coupled receptors (GPCRs), 4:366–367
 - ion channels, 4:367–368, 4:367f
 - salty taste receptors, 4:367–368
 - sour taste receptors, 4:367–368
 - sweet taste receptors, 4:366–367
 - T1R1 receptors, 4:366–367, 4:367f
 - T2R receptors, 4:367, 4:367f
 - taste buds, 4:366, 4:367f
 - taste receptor cells (TRCs), 4:366, 4:367f
 - transduction cascades, 4:368
 - umami taste receptors, 4:366–367
- Tata, 4:51f, 4:54
- TATA-binding protein (TBP)
- GAL1–10 gene expression, 1:525, 1:526f
 - gene transcription regulation, 4:234
 - RNA polymerase II (Pol II), 4:163
- tau proteins
- basic concepts, 1:477–478
 - bundle formation, 3:106f
 - characteristics, 3:104t, 3:105, 3:105f
 - glycogen synthase kinase-3 (GSK3), 2:436t, 2:437
 - isoforms, 1:476f
 - neurodegenerative diseases, 3:106–107
 - neurogenerative disorders, 1:477t
 - tau mutations, 1:475–477
- Tauri disease, 2:431t, 2:432
- taxol, 4:450–451
- Tay–Sachs disease, 4:291t, 4:507–508, 4:507t
- T-box transcription factor family, 1:184, 1:184f
- T-brain gene-2 (Tbr-2), 1:196–197, 1:197f
- T cells
- anti-mitochondrial antibodies (AMAs), 3:115–116
 - calcineurin-mediated signal transduction, 1:312, 1:339–340, 1:340f
 - calcium ion (Ca^{2+}) release-activated Ca^{2+} channels (CRAC), 1:127–128
 - calcium oscillations, 1:323–324
 - chemokine receptors, 1:484
 - diacylglycerol kinases (DGKs), 1:661–662
 - exosomes and microvesicles (EMVs), 2:264
 - $\text{G}_{12}/\text{G}_{13}$ family functions, 2:345t

research summary, 3:209
transmembrane proteins, 3:207t
- transport and metabolism regulation, 3:208–209
- utrophin, 2:625–627
- UvrABCD system, 3:328–336
bacteria–human conservation model, 3:336
damage recognition mechanisms
general discussion, 3:333–334
padlock model, 3:334–335
UvrA₂–DNA complex, 3:333
UvrA₂B₂ complex in solution, 3:333
UvrA₂–DNA binding, 3:333
UvrA dimerization, 3:333
UvrB–DNA intermediate complex
formation, 3:333–334
damage sensing mechanisms
basic concepts, 3:334–335, 3:334f
DNA polymerase I, 3:335
dual incision step, 3:334
LexA regulatory protein, 2:709–710
postincision steps, 3:334
UvrB–DNA complex, 3:334–335, 3:334f
UvrD, 3:334
DNA mismatch repair (MMR), 2:41f, 2:45–46, 2:67
functional role, 2:54–56, 2:55t, 2:56f
protein properties
UvrA, 3:330–332, 3:332f
UvrB, 3:332, 3:332f
UvrC, 3:332, 3:333f
substrate ranges, 3:330t
transcription-coupled repair (TCR), 3:335–336, 3:335f
UvrABCD endonuclease, 3:328, 3:329f, 3:330t
- UvrD helicases
characteristics and functional role, 3:261
damage sensing mechanisms, 3:334
DNA unwinding
active, rolling or hand-over-hand
model, 3:264–265, 3:265f
active versus passive mechanisms, 3:264
dimeric inch-worm models, 3:265, 3:265f
inch-worm mechanisms, 3:264, 3:264f, 3:265f
protein oligomerization, 3:263
unwinding mechanisms, 3:263–264
research summary, 3:265
single-strand DNA (ssDNA)
translocation, 3:263, 3:264, 3:264f
structural characteristics
crystal structures, 3:262, 3:262f
open and closed confirmations, 3:262–263
primary structures, 3:261–262
translocase-based protein displacement, 3:265
- uvr* genes
Cho, 3:330, 3:331f
historical research, 3:328–330
uvrA, 3:328, 3:329f
uvrB, 3:329f, 3:330
uvrC, 3:329f, 3:330, 3:331f
UvsX/UvsY proteins, 4:23–24, 4:37, 4:37f
- V**
- vaccine adjuvants, 4:399–400
- vacuolar (H⁺)-ATPases, 4:520–524
functional role
intracellular V-ATPases, 4:520, 4:521f
plasma membrane V-ATPases, 4:520–521
in vivo activity regulation, 4:523
structural characteristics, 4:521–523, 4:522f
subunit composition, 4:522t
transport mechanisms, 4:523
- vacuolar protein sorting 4 (Vps4) protein, 1:3t, 1:5–6
- vacuoles, 4:502–508
characteristics and functional role, 4:502–503, 4:503f, 4:504f
eukaryotic functions
disease connections, 4:507–508, 4:507t
lysosome-related organelles, 4:506–507
pathogen-containing vacuoles, 4:507
protozoan contractile vacuole complex, 4:506
historical research, 4:502–503
yeasts
biogenesis, 4:503–506
characteristics, 4:502–503, 4:503f
functional role, 4:503, 4:504f
transport pathways
AP-3 pathway, 4:505f, 4:506
autophagy/macro-autophagy, 4:505f, 4:506, 4:506f
characteristics, 4:503–506, 4:505f
Vps pathway, 4:504–506, 4:506f
- valine
anaplerotic pathways, 1:106f
classifications, 1:92t
degradative pathways, 1:244, 1:245f
elastin, 2:192
leucine–aspartic acid–valine (LDV)
peptide, 2:608
phage libraries, 3:434t
starvation effects, 4:302
- valitocin, 4:516t
- valproate, 2:292
- Van Hippel Lindau (VHL) substrate model, 1:459
- varafenil, 1:569
- VARICOSE (VCS) gene, 3:100
- variegate porphyria, 2:542t
- vascular endothelial growth factor (VEGF)
cadherin signaling, 1:264
matrix metalloproteinases (MMPs), 3:96
neurogenesis, 1:197f, 1:198, 1:200f
nuclear factor kappa B (NF- κ B), 3:304t
transient receptor potential (TRP)
channels, 4:415
- vascular endothelial growth factor
receptors (VEGFRs), 4:509–514
biological activity
embryonic development, 4:512–513
lymphangiogenesis, 4:513
neovascularization, 4:513
nonmitogenic functions, 4:513–514
evolutionary development, 4:509

- gene expression regulation
 general discussion, 4:509–510
 VEGFR-1, 4:509
 VEGFR-2, 4:509
 VEGFR-3, 4:509–510
- ligand binding
 co-receptors, 4:511
 receptor binding, 4:510–511, 4:511f
 VEGF structure, 4:510–511, 4:511f
- protein structure
 characteristics, 4:510
 extracellular domains, 4:510, 4:510f
 intracellular domains, 4:510, 4:510f
 transmembrane domains, 4:510, 4:510f
- research summary, 4:514
- signal transduction
 receptor tyrosine kinase activation, 4:511, 4:512f
 signaling protein recruitment, 4:511–512
 signal transduction cascades, 4:512
 structural characteristics, 4:509
- von Hippel–Lindau protein (VHL), 4:570
- vascular endothelium
 adiponectin, 3:74
 aquaporin water channels, 1:124t
 blood-clotting proteases, 3:586f, 3:587
 leukotriene receptors, 3:584
- vascular smooth muscles, 2:345t
- vas deferens, 1:124t
- vasoactive intestinal polypeptide (VIP), 1:272
- vasopressin, 4:515–519
 ascorbic acid, 4:531–532
 evolutionary development, 4:516f
 functional role, 4:515–517
 G-protein-coupled receptors (GPCRs), 2:344t
 peptide amidation, 3:396
 peptide biosynthesis, 4:515
 receptors, 4:517–519, 4:518f
 structural characteristics, 4:515
 transmembrane domains, 4:517–519, 4:518f
 types and sources, 4:516t
- vasotocin, 4:516t
- VASP/Ena (EHAH) proteins, 1:28–29, 1:29–31, 1:29f, 1:30f, 1:19–20, 2:320–321, 2:320f
- V(D)J recombination, 3:272, 3:272f
- veal, 4:533t
- vectorial redox loop, 1:468–469, 1:469f
- vegetables, 4:533t, 4:547–548
- venomous peptides, 4:551
- ventromedial hypothalamus (VMH), 2:260, 3:77–78, 3:78f
- venturicidin, 1:143t
- Venus flytrap (VFT) domain, 2:396
- veratridine, 4:568t
- versican, 3:657t, 3:658
- vertebrates
 calpains, 1:354f
 lectins, 2:701, 2:702t, 2:704t
 matrix metalloproteinases (MMPs), 3:90, 3:91t
- nicotinic acid adenine dinucleotide phosphate (NAADP)-induced calcium ion (Ca^{2+}) release, 2:638, 2:638t
- vasopressin/oxytocin family, 4:516t
- very long-chain acyl-CoA dehydrogenase (VLCAD), 1:385f
- very long-chain acyl-CoA synthetase (VLCAS), 2:293–294
- very low density lipoproteins (VLDLs)
 diabetes, 1:655
 insulin metabolism, 2:606–607
 lipogenic gene expression, 2:287f
 peroxisome proliferator-activated receptors (PPARs), 3:418
 starvation effects, 4:303–304
 vitamin E, 4:548
- very-short patch (VSP) repair
 homologous recombination (HR), 2:46f
 research background, 4:76
- vsr* genes
 biochemistry, 4:76–77
 mutagenesis, 4:77
 structure and regulation, 4:76, 4:77f
- very strong (single-well) hydrogen bonds
 bond lengths, 2:757
 deuterium fractionation factors, 2:758
 spectroscopic properties, 2:758
 structural characteristics, 2:757, 2:757f
- Veterans Affairs Diabetes Trial (VADT), 3:423
- Viagra, 1:569
- Vibrio*, 2:43
- Vibrio anguillarum*, 4:251
- Vibrio cholerae*
 adenosine diphosphate ribosylation factors (ARF), 1:134–135
 chemotaxis receptor fibers, 3:607–608
 Cho phylogenetic tree, 3:331f
 G_s family, 2:519
 LexA regulatory protein, 2:710–711
 tyrosine recombinases, 1:558, 1:558f
uvrC phylogenetic tree, 3:331f
- Vibrio fischeri*, 1:465, 1:572
- Vibrio parahaemolyticus*, 2:14, 2:388, 2:389f
- villin, 1:23–24, 1:277–278
- vimentin, 1:47, 2:625–627, 2:632t, 2:634, 3:233
- vinblastin, 1:150t
- vinculin, 2:320–321, 2:320f
- vinexin, 2:320–321
- violaxanthin
 chemical properties, 1:504
 light harvesting process
 energy dissipation, 3:493
 nonphotochemical energy dissipation, 2:181f
 protein components, 2:726–727
 reaction centers, 2:178
 structural characteristics, 2:179f
 xanthophyll cycle, 2:180–181, 3:486–487, 3:487f
 molecular structure, 1:502f
- viral fusion proteins
 characteristics and functional role, 3:38
 class I fusion proteins, 3:39–41, 3:39f
 class II fusion proteins, 3:39f, 3:41
 class III fusion proteins, 3:40f, 3:41–42
- viral RNAs, 4:156–157
- viral src gene (v-src), 4:293–294
- viroldamine, 2:195f
- viruses
 DNA replication, 2:108–109
 hexameric enzyme helicases, 2:26
 lectins, 2:701, 2:702t, 2:704t
 non-homologous end joining (NHEJ), 3:268
 nuclear factor kappa B (NF- κ B), 3:303t, 3:304t
 ribozyme distribution, 4:146f
 sliding clamp processivity, 4:240, 4:240f
See also human immunodeficiency virus (HIV-1)
- vitamin A, 4:525–529
 chemical and metabolic reactions, 4:525–526, 4:526t
 clinical uses, 4:529
 functional roles, 4:525
 homeostasis control mechanisms, 4:529
 naturally occurring retinoids, 4:529
 pharmacological retinoid concentrations, 4:528–529
 retinoid-binding proteins (RBPs), 4:526–528, 4:527f, 4:527t
 retinoid homeostasis, 4:526–528
- vitamin B₁, 1:202–209
 adenosine thiamine triphosphate (AThTP)
 derivative determinations, 1:204, 1:204f
 metabolic pathways, 1:205f, 1:206
 molecular structure, 1:203f
 non-cofactor roles, 1:207–208
 background information, 1:202
 biosynthesis, 1:203–204
 chemical properties, 1:202–203, 1:204f
 derivative determinations, 1:204, 1:204f
 metabolic pathways
 adenosine thiamine triphosphate (AThTP), 1:205f, 1:206
 general discussion, 1:206
 thiamine diphosphate (ThDP), 1:205, 1:205f
 thiamine triphosphate (ThTP), 1:205–206, 1:205f
 molecular structure, 1:203f
 non-cofactor roles, 1:207–208
 related diseases
 beriberi, 1:202, 1:208
 nutritional deficiencies, 1:208–209
 transport defects
 Amish lethal microcephaly, 1:209
 Leigh disease (subacute necrotizing encephalomyelopathy), 1:209
 maple syrup disease, 1:209
 thiamine-responsive megaloblastic anemia (TRMA), 1:209
 Wernicke–Korsakoff syndrome, 1:202, 1:208–209
 research summary, 1:209
 riboswitches, 1:203–204
 thiamine-binding proteins, 1:206
 thiamine diphosphate (ThDP)
 background information, 1:202
 catalytic reaction mechanisms, 1:206–207, 1:208f

- vitamin B₁ (*Continued*)
 cofactor role, 1:206, 1:207f
 derivative determinations, 1:204f
 hydrolysis mechanisms, 1:206
 α -lactyl-ThDP, 1:206–207, 1:208f
 metabolic pathways, 1:205, 1:205f
 molecular structure, 1:203f
 prevalence, 1:204
 pyruvate dehydrogenases (PDHs), 4:321–322, 4:325f
 thiamine monophosphate (ThMP)
 biosynthetic pathway, 1:203–204
 derivative determinations, 1:204f
 hydrolysis mechanisms, 1:206
 metabolic pathways, 1:205f
 molecular structure, 1:203f
 thiamine triphosphate (ThTP)
 derivative determinations, 1:204, 1:204f
 hydrolysis mechanisms, 1:206
 metabolic pathways, 1:205–206, 1:205f
 molecular structure, 1:203f
 non-cofactor roles, 1:207–208
 transport mechanisms, 1:205
 vitamin B₁₂, 1:155–160, 2:324–328
 absorption and transport, 2:327
 acetogenesis, 1:159–160
 biochemistry, 2:327
 catalytic reactions
 carbon skeleton rearrangement reactions, 1:157, 1:157f, 1:158t
 methyl transfer reactions, 1:156f, 1:158–159, 1:159f
 migration and elimination reactions, 1:156, 1:157f, 1:158t
 pyridoxal 5'-phosphate (PLP)-dependent aminomutase reactions, 1:157, 1:157f, 1:158t
 radical-mediated rearrangement reactions, 1:156, 1:157f, 1:158t, 2:327
 ribonucleotide triphosphate reductase, 1:157f, 1:158, 1:158t
 chemical characteristics and structure, 2:326, 2:326f
 cobalamin cofactor, 1:155–156, 1:156f
 cobalamin-dependent methionine synthase, 1:159, 1:159f
 coenzyme B₁₂, 3:544
 deficiency-related diseases, 2:328
 functional role
 metabolic reactions, 2:327
 methionine synthase, 2:327
 methylmalonyl CoA mutase, 2:327
 gastric secretions, 2:356
 methanogenesis, 1:159–160
 structural characteristics, 1:156f
 vitamin B₂
 chemical properties, 2:309
 importance, 2:309
 molecular structure, 2:310f
 vitamin B₆
 characteristics and functional role, 3:708
 molecular structure, 3:709f
 vitamin C, 4:530–534
 background information, 4:530
 biochemical importance, 4:531–532
 cellular regulation, 4:532–533
 chemical properties, 4:531, 4:531f
 detection methods, 4:533
 digestion and absorption, 4:533
 nutritional importance, 4:531–532
 nutritional requirements, 4:533
 peptidylglycine α -hydroxylating monooxygenase (PHM), 3:396
 recommended dietary allowance (RDA), 4:533–534
 research summary, 4:534
 sources, 4:533t
 vitamin D, 4:535–539
 characteristics and functional role, 4:540
 chemical identity, 4:535, 4:536f
 cholesterol biosynthetic pathway, 1:516, 1:517f
 1 α ,25-dihydroxyvitamin D₃ (1,25-(OH)₂D₃)
 action mechanisms, 4:541f
 calbindin-D_{9k}
 intestines, 1:288
 regulation mechanisms, 1:288
 calbindin-D_{28k}
 intestines, 1:284
 kidneys, 1:285
 regulation mechanisms, 1:286
 calcium homeostasis, 1:328–329
 characteristics and functional role, 4:308–309
 chemical structure, 4:309f
 degradation pathways, 4:538
 endocrine regulation, 4:537
 functional roles, 4:538–539
 hormonal conversion process, 4:535–536, 4:536f
 metabolism, 4:538
 molecular mechanisms, 4:537–538, 4:538f
 negative VDREs (nVDREs), 4:542–543
 plasma calcium and phosphorus regulation, 4:536–537, 4:537f
 therapeutic uses, 4:539
 vitamin D receptor (VDR), 4:311, 4:537, 4:543–544, 4:543f
 vitamin D-response elements (VDREs), 4:311f, 4:537–538, 4:538f, 4:542–543
 endocrine regulation, 4:537
 functional roles, 4:538–539
 hormonal conversion process, 4:535–536, 4:536f
 negative VDREs (nVDREs), 4:542–543

 vitamin H, 1:221–225
 biotin domains
 characteristics, 1:222–223
 sequence alignment, 1:223f
 structural characteristics, 1:223–224, 1:223f
 biotin enzymes, 1:221–222, 1:222f
 biotin-mediated carboxyl transfer reactions, 1:222f
 biotin protein ligase (BPL)
 biotin-inducible repressor (BirA), 1:224, 1:224f
 biotinylated proteins, 1:226
 reaction mechanisms, 1:224
 characteristics, 1:221
 protein biotinylation, 1:226–228
 analytical and clinical applications, 1:226
 basic concepts, 1:226
 biosynthesis, 1:226
 biotinylated antibodies, 1:227–228
 chemical synthesis, 1:227, 1:227f
 medical importance, 1:226–227
 research background, 1:221
 vitamin K, 4:551–554
 biochemical role, 4:551–553
 chemical characteristics, 3:727–728
 deficiency-related diseases, 4:554

- functional role, 3:728, 3:728f
 metabolic interconversion, 4:553–554, 4:553f
 nutritional role, 4:554
 vitamin K-dependent carboxylase, 4:551–553, 4:552f
 vitamin K-dependent proteins, 4:551
 vitamin malabsorption, 3:564
 vitellogenesis, 2:592–593
 vitronectin (VN)
 cell–matrix interactions, 1:413f, 1:426, 1:427t, 1:438–440
 focal adhesion kinase (FAK) family, 2:265–266
 integrins, 1:427t, 1:438–440
 matrix metalloproteinases (MMPs), 3:91t
 voltage-dependent anion-selective channels (VDACs)
 functional role, 3:161
 mammalian low- K_m hexokinases, 2:546
 mitochondrial CK (MtCK) isoenzyme, 3:82–84, 3:83f
 mitochondrial DNA (mtDNA), 1:212f
 mitochondrial outer membrane, 1:350–351, 3:127–128, 3:128t, 3:130f, 3:159
 mitochondrial permeability transition pore, 3:163
 structural characteristics, 3:160–161, 3:160f
 voltage-dependent calcium channels (VDCCs), 2:597f
 vomiting
 dopamine receptors, 2:173
 hyperammonemia, 4:494
 neuromin-1 receptor (NK1R), 4:364
 von Gierke disease, 2:383, 2:427t, 2:431, 2:431t
 von Hippel–Lindau protein (VHL), 4:570–571
 functional role, 4:570, 4:571f
 HIF-1 α level regulation, 4:69
 mutation consequences, 4:570
 ubiquitin ligase
 functional role, 4:570, 4:571f
 hypoxia inducible factor (HIF) regulation, 4:571
 structural characteristics, 4:570–571, 4:571f
 von Willebrand factor (vWF)
 cell–matrix interactions, 1:426, 1:427t
 integrins, 1:427t
 VPS34/Vps34p gene complex, 3:447–448, 3:448f, 3:450
 vSrc protein, 4:293–294
vsr genes
 biochemistry, 4:76–77
 mutagenesis, 4:77
 structure and regulation, 4:76, 4:77f

 pyruvate kinase (PK), 3:721
 Warburg, Otto, 4:436
 warfarin, 3:588–589, 4:553–554, 4:553f
 water
 aquaporin water channels, 1:120–126
 aquaglyceroporins, 1:123–125, 1:124f
 aquaporin-1 (AQP1)
 arginine vasopressin (AVP) regulation, 1:123, 1:123f
 functional expression, 1:121f
 historical research, 1:120
 membrane topology, 1:122f
 physiological functions, 1:121–123, 1:123f
 sagittal cross-section schematic diagram, 1:122f
 structural characteristics, 1:120–121, 1:122f
 aquaporin-2 (AQP2), 1:123, 1:123f
 distribution and permeability, 1:123–125, 1:124t
 evolutionary relationships, 1:124f
 mammalian aquaporin homologs, 1:123–125, 1:124t
 research summary, 1:125
 water transport mechanisms, 1:120, 1:121f
 metalloproteases, 3:87–88
 water transport mechanisms, 1:120, 1:121f
 WAVE proteins, 1:440–441, 1:441f, 4:113
 waxes, 2:291f
 WBSCR 14 syndrome, 1:374
 WD (tryptophan (W)-aspartic acid (D) dipeptide) domain, 1:24
 weak hydrogen bonds
 bond lengths, 2:757
 deuterium fractionation factors, 2:758
 spectroscopic properties, 2:757
 structural characteristics, 2:756, 2:757f
 Werner's syndrome
 characteristics, 4:46
 DNA secondary structures, 2:147
 hexameric enzyme helicases, 2:26
 mutation effects, 4:44
 nicotinamide adenine dinucleotide (NAD⁺/NADH), 1:177
 Wernicke–Korsakoff syndrome, 1:202, 1:208–209, 3:394
 wheat
 lectins, 2:702t
 retrotransposons, 3:284f
 wheat germ, 2:704t
- white adipose tissue (WAT), 1:583, 2:259, 2:518–519
 Williams–Beuren syndrome, 1:374
 Wilms' tumor, 3:657t
wilm's tumor associated protein (wtap) gene, 1:84
 Wilson's disease, 3:670–671
 Wiskott–Aldrich syndrome protein (WASP)
 family, 1:29, 1:20, 1:21f, 1:26, 3:438–439, 4:113, 4:114f
 Wnt pathway
 adipocyte development, 1:53–54, 1:53f
 cardiac muscle development, 1:183–184, 1:184f
 fibroblast growth factor 8 (FGF8), 2:306
 liver regeneration, 1:192f
 neurogenesis, 1:197f
 parathyroid hormone (PTH), 3:385–386
 protein palmitoylation, 2:736–737, 3:645–646
 telomeres, 4:386
 Wnt/ β -catenin signaling pathway, 1:263–264, 1:263f, 2:434–435, 2:436f, 3:385–386, 4:386
Wolbachia sp, 3:331f
Wolinella, 2:207f, 2:208f, 3:30
Wolinella succinogenes, 3:30, 4:92–93, 4:94f, 4:95f
 woolly hair syndrome, 1:638t
 Woronin body, 3:425
 wortmannin, 1:150t, 3:274
 wwPDB database, 3:615t
- X**
- XAB2 protein, 4:404
 xanthine oxidase, 2:77, 2:312, 2:590
Xanthomanas campestris, 3:350–351
 xanthophylls, 2:178–179, 2:726–727, 3:486–487, 3:487f
 xanthopterin, 3:667f
 XBP-1 gene expression, 2:524–525, 2:524f
 X-chromosome inactivation, 1:522
Xenopus laevis
 adenosine-to-inosine (A-to-I) RNA editing, 4:154–155
 aquaporin water channels, 1:120, 1:121f, 1:125
 calpains, 1:359
 DNA replication, 2:109–110
 kinesins, 2:674
 origin recognition complex (ORC), 2:111
 RecQ helicases, 4:43–44, 4:44f
 small RNAs (sRNAs), 3:98
 voltage-gated potassium channels, 4:559
Xenopus tropicalis, 2:5t
 XerC/XerD/*dif* system, 1:555–556, 1:558f, 1:561
 xeroderma pigmentosum (XP)
 hexameric enzyme helicases, 2:26
 nucleotide excision repair (NER), 3:339–340, 4:404
 polymerase η (Pol η), 4:481, 4:572–574
 ultraviolet (UV) damage, 4:572
 X-linked adrenoleukodystrophy, 3:415–416

X-linked dominant protoporphyria, 2:542, 2:542t
 X-linked sideroblastic anemia, 2:542t
 XPC protein complex, 3:341–342, 3:342f, 3:342t
 XPG protein complex, 3:342f, 3:342t, 3:343–344, 3:343f
 X-ray absorption spectroscopy, 2:661–662
 X-ray cross-complementing factor-1 (XRCC1), 2:85–86
 X-ray crystallography, 3:11, 4:129–130
 XRCC1 protein, 2:4f, 2:6, 2:30–31, 2:30t
 XRCC4-like factor (XLF), 3:271, 3:273t
 XRCC4 protein, 3:271, 3:272f, 3:273t
Xylella fastidiosa, 3:331f
 xylitol, 2:387
 xylose
 O-linked glycosylation, 2:466f
 structural characteristics, 3:654
 O-xylose, 2:453
 α 1,3-xylosyltransferase (α 3XylT), 2:454f
 xylulose-5-phosphate (Xu-5-P)
 carbohydrate-responsive element binding protein (ChREBP), 1:375–376, 1:376f, 1:377f
 pentose phosphate pathway
 carbon fate, 3:394f
 chemical balance, 3:394f
 nonoxidative reactions, 3:391, 3:393f
 oxidative reactions, 3:391–392
 photosynthetic metabolic pathways, 3:499f
 thiamine diphosphate (ThDP), 1:207f

Y

Yarrowia lipolytica
 peroxisomal matrix protein import, 3:426–429
 respiratory chain complex I (NADH: ubiquinone oxidoreductase), 4:88, 4:89t, 4:341–342
 yeasts
 budding yeasts, 4:31–32, 4:216–217, 4:216f
 calpains, 1:354f
 conventional actin, 1:38–40
 cytochrome *c*, 1:600, 1:600f
 exon–intron architecture, 3:142–144, 3:143f, 4:186–187
 fission yeasts, 4:217–218
 glycosylphosphatidylinositol (GPI)-anchored proteins, 2:477–478
 macroautophagy
 Atg proteins, 1:151–153, 1:152t
 cytoplasm-to-vacuole targeting (Cvt) pathway, 1:151, 1:151f
 model systems, 1:150–151
 molecular mechanisms, 1:151–153
 Atg proteins, 1:151–153, 1:152t
 cargo selection, 1:153
 fusion and breakdown, 1:153
 phagophore assembly site (PAS), 1:152
 regulatory mechanisms, 1:152–153
 microautophagy

mitophagy, 1:153
 nonselective microautophagy, 1:153
 pexophagy, 1:153
 mitochondrial DNA (mtDNA), 3:134t
 DNA replication, 2:128
 gene expression, 3:140–144
 basic process, 3:140–141, 3:141f
 encoding processes, 3:140
 5'-end–RNase P process pathway, 3:142, 3:142f
 model systems, 3:140, 3:141f
 mosaic mitochondrial genes, 3:142–144, 3:143f
 RNA splicing, 3:142–144, 3:143f
 3'-end–RNase process pathway, 3:142, 3:142f
 transcription processes, 3:141, 3:141f, 3:142f
 translation processes, 3:144
 nucleoporin proteins (Nups), 3:319f, 3:320t
 pheromone receptors, 3:441–446
 conformational constraints, 3:445
 conjugation functions, 3:441, 3:442f
 G-protein activation, 3:445–446
 ligand binding, 3:444–445
 receptor biogenesis, 3:443–444, 3:444f
 regulatory mechanisms, 3:442–443, 3:443f, 3:444f
 signal transduction pathways, 3:441–442, 3:443f
 spatial gradient sensors, 3:442
 phospholipase D (PLD), 3:473
 phospholipid synthesis, 3:478–481
 basic process, 3:478
 cytidine diphosphate (CDP)–choline pathway, 3:479f, 3:480
 cytidine diphosphate (CDP)–diacylglycerol (DAG) pathway, 3:478–480, 3:479f
 cytidine diphosphate (CDP)–ethanolamine pathway, 3:479f, 3:480
 major phospholipids, 3:478, 3:479f
 phosphatidate (PA) synthesis, 3:478
 phosphatidylglycerolphosphate (PGP), 3:480
 regulation mechanisms
 biochemical regulation, 3:481
 general discussion, 3:480
 genetic regulation, 3:480–481
 plasma membrane proton (H^+)-ATPases, 3:688
 prions, 3:566–570
 chaperone functions, 3:569
 disease states, 3:568–569
 functional domains, 3:566–567, 3:568f
 generation mechanisms, 3:569
 genetic criteria, 3:566, 3:567f
 known prions, 3:566
 prion domains, 3:566–567, 3:568f
 research summary, 3:569–570
 self-propagating amyloidosis, 3:567–568, 3:568f
 protein biosynthesis elongation, 2:253

recombination-dependent DNA replication (RDR), 4:24–25
 retrotransposons, 3:283, 3:284f
 ribozyme distribution, 4:146f
 secretory pathway, 3:690, 3:690f
 septins
 budding yeasts, 4:216–217, 4:216f
 fission yeasts, 4:217–218
 superoxide dismutases (SODs), 4:353
 two-hybrid protein–protein interaction systems, 4:460–462
 basic concepts, 4:460–462, 4:461f
 proteomic studies, 4:462
 research applications, 4:461–462
 reverse two-hybrid systems, 4:461–462
 unfolded protein response (UPR)
 HAC1 gene expression, 4:489, 4:490f
 inositol requiring 1 (IRE1) genes, 4:489, 4:490f
 vacuoles
 biogenesis, 4:503–506
 characteristics, 4:502–503
 functional role, 4:503, 4:504f
 transport pathways
 AP-3 pathway, 4:505f, 4:506
 autophagy/macro-autophagy, 4:505f, 4:506, 4:506f
 characteristics, 4:503–506, 4:505f
 Vps pathway, 4:504–506, 4:506f
